The patients and their families should have instructions for such instances. Every patient should wear a medical identification (e.g., MedicAlert) bracelet or necklace and carry the emergency medical information card that is supplied with it. Both should

Case Study

A 3-week-old phenotypic male newborn presented with lethargy, poor oral intake, and progressive vomiting for 1 week. He refused to eat over the previous 7 hours. There was no history of fever. Prenatal history was unremarkable. Birth history: normal vaginal delivery, Apgar scores of 8 and 9 with a birthweight of 8 pounds, 14 ounces (4.03 kg). The newborn examination performed in the nursery identified perineal hypospadias, but the newborn was discharged home on day 2 of life. Over the first 2 weeks of life, weight gain was poor, and appetite was markedly decreased over the 1 to 2 days before evaluation in the emergency department. Family history revealed that he was the second child of the family, from a nonconsanguineous marriage of Chinese background. (The first boy died at 1 month of age in China because of gastroenteritis.) On examination, vital signs were body temperature, 36.5°C; blood pressure, 52/32 mmHg; pulse, 160 beats/min. He was severely dehydrated. There was no hyperpigmentation. The physical examination was notable for a weight of 3.1 kg and a phallus with a length of 2.5 cm, a midshaft diameter of 1.5 cm with hypospadias near the perineum, a hyperpigmented and rugated shawl scrotum, and no palpable testes. Initial blood glucose level was 40 mg/dL. The infant's mental status was improved after fluid and dextrose administration via an intraosseous line. Resuscitation was continued with dextrose containing normal saline. Initial laboratory values showed sodium of 107 mmol/L, potassium of 7.1 mmol/L, chloride of 87 mmol/L, and total CO₂ of 5.0 mmol/L. Blood urea nitrogen was 40.5 mg/dL, and creatinine was 0.6 mg/dL. After the critical blood sample

was obtained, the newborn was given 100 mg/m² of IV hydrocortisone. Additional evaluation revealed 46,XX chromosomes and enlarged adrenals, as well as a small uterus on ultrasound examination. The clinical course was complicated by necrotizing enterocolitis that led to a stay in the hospital for 3 weeks with conservative management including administration of antibiotics. Initial laboratory results noted 17-OHP of 111,000 ng/dL, ACTH of 4755 pg/mL, and cortisol 3.9 µg/dL before hydrocortisone treatment (no ACTH stimulation performed). Aldosterone and renin analyses were not performed because of the difficulty in obtaining adequate blood. *CYP21A2* analysis revealed a genotype as follows: exon1, intron2, and exon3/intron2 mutations (<1% of enzyme activity in vitro for both mutations). This case is a classic presentation of the salt-wasting form of 21-OHD CAH.

Comment

The lesson learned from this case is that in a phenotypic male without palpable testes, the genitourinary anomalies should be considered ambiguous genitalia. Further work-up is merited in the immediate perinatal period. Family history suggests a severe recessive disorder. Genetic analysis is available and can be used to confirm the diagnosis before lifetime therapy and is of value in genetic counseling. In addition, the institution of newborn screening for elevated 17α-hydroxyprogesterone allows earlier detection of salt-wasting 21-hydroxylase deficiency, before the occurrence of a life-threatening event.

CONTROVERSY BOX

Prevention of prenatal virilization in affected females is possible with a proper prenatal diagnosis and treatment program. In families where the risk of having a baby girl with congenital adrenal hyperplasia (CAH) is one in eight, the disease can be diagnosed prenatally through molecular genetic analysis of fetal DNA. Appropriate prenatal treatment by dexamethasone administration to the pregnant mother carrying an at-risk fetus before 6 weeks post conception is effective in reducing virilization in the genetic female, making postnatal genitoplasty unnecessary and thereby avoiding potential impairment of sexual function (Fig. 96.5A–B). At 7–10 weeks, cell-free DNA testing may allow for discontinuation of the dexamethasone if an XY fetus is identified. After diagnosis is made by fetal DNA analysis obtained from chorionic villus sampling at 10 to 12 weeks' gestation, therapy in unaffected or male fetuses is discontinued (Nimkarn and New, 2006). Some believe there are accurate, compelling data from the largest human studies (Forest et al., 1989; Mercado et al., 1995; New et al., 2001) indicating the benefit of prenatal treatment and that it is safe in the short

term for both the fetus and the mother. Some preliminary data from long-term studies also support these results (Nimkarn and New, 2009), although long-term follow-up studies are still under way. Studies from Sweden, however, found that children without CAH treated prenatally with dexamethasone had decreased verbal working memory and decreased self-perception of scholastic ability. Those with CAH had decreased verbal processing speed that normalized though when adjusted for intelligence quotient (Hirvikoski et al., 2007; Lajic S et al., 2011). The ethics of prenatal dexamethasone therapy remains controversial because of unknown long-term outcomes and because seven fetuses were treated unnecessarily. Dexamethasone therapy also incurs maternal risk. Consequently, multiple endocrine societies consider prenatal dexamethasone therapy to be experimental and that it should only be performed in a research environment with long-term outcome studies, as the risk for long-term effect is not known (Speiser et al., 2010).

• **Fig. 96.5** Two Sisters With Congenital Adrenal Hyperplasia. (A) Female infant with congenital adrenal hyperplasia. There is enlargement of the clitoris with fusion and rugation of labial scrotal folds. (B) Sister of the female infant in (A) who also has congenital adrenal hyperplasia but whose mother received dexamethasone therapy prenatally to prevent virilization of external genitalia. (From Forest MG, Morel Y, David M. Prenatal treatment of congenital adrenal hyperplasia. *Trends Endocrinol Metab.* 1998;9:284–289.)

indicate the diagnosis, the daily medications and doses, and the physician to call in the event of an emergency.

Secondary or Tertiary Adrenal Insufficiency

Cortisol replacement for patients with secondary or tertiary adrenal insufficiency is the same as described for patients with primary adrenal insufficiency. To minimize growth suppression, these children can be treated with doses of hydrocortisone that are slightly less than physiologic replacement doses. Furthermore, because mineralocorticoid production is under the control of the renin-angiotensin system, patients with secondary or tertiary adrenal insufficiency do not require mineralocorticoid replacement. However, these infants require evaluation for deficiencies of other pituitary hormones.

Disorders of Sexual Differentiation

MARGARETT SHNORHAVORIAN AND PATRICIA Y. FECHNER

KEY POINTS

- Differences in sex development (DSD) are due to many different causes that have important consequences for long-term outcome and require the expertise of the pediatric endocrinologist, pediatric urologist, geneticist, and child psychologist as well as the adolescent gynecologist, cytogeneticist, radiologist, and ethicist in some cases to aid in the diagnosis and treatment of infants with DSD.
- Understanding normal sex development males and females is critical to determining the cause of DSD.
- Genetic testing has advanced our understanding of the origins of sex development, and specific testing may be driven by results of hormonal testing. In other situations the differential diagnosis for a given condition such as complete gonadal dysgenesis is so large that the use of a DSD panel is necessary. Knowing the genetic diagnosis provides closure for families and identifies other risks associated with the diagnosis, such as recurrence, renal disease, or tumor risk. A genetic diagnosis may also predict outcome at puberty.

“Is it a boy or a girl?” is often the first question asked when a baby is born. For parents of a newborn with genitalia that are not clearly male or female, the ambiguity is a distressing matter that needs to be addressed with sensitivity and some urgency. There are four general classifications that can cause disorders of or differences in sex development (DSD): (1) virilization of the 46,XX individual, (2) incomplete virilization of the 46,XY individual, (3) sex gonadal differentiation and chromosomal disorders, and (4) syndromes associated with incomplete genital development ([Box 97.1](#)). The first category, 46,XX DSD, comprises the majority of definable cases of ambiguous genitalia, whereas in the second category, 46,XY DSD, a genetic diagnosis is feasible in less than 50% of cases.

This chapter presents an overview of the pathophysiology of DSD, including a discussion of the practical aspects of diagnosis and management. An overview of the traditional surgical methods used in the treatment of infants with DSD, including the risks and benefits of these procedures, is included at the end of the chapter.

General Considerations in the Approach to the Newborn With Ambiguous Genitalia

The medical evaluation of a newborn with ambiguous genitalia is necessarily time consuming. Open and honest discussions with

the parents are invaluable in allaying anxiety and establishing a trusting relationship. Full disclosure of available information is essential in this regard.

Care must be taken to avoid premature sex assignment for the infant. Proper evaluation of the infant with ambiguous genitalia requires a multidisciplinary team that should include the primary care physician, neonatologist, pediatric endocrinologist, psychologist, pediatric urologist, pediatric geneticist, and pediatric radiologist ([Moshiri et al., 2012](#)). Psychologic assessment and support of the family are essential in the newborn period, along with long-term psychologic follow-up evaluation ([Slijper et al., 1998](#); [Hines, 2004](#); [Guerra-Junior and Maciel-Guerra, 2007](#)). Decisions regarding the sex of rearing should be made collaboratively between the multidisciplinary team and the parents, with the recognition that cultural and psychosocial factors play a role ([Grumbach and Conte, 1998](#); [Kuhnle and Krahle, 2002](#)).

In the past, sex assignment was based largely on phallus size, relative ease of surgical reconstruction, or the potential for fertility. This approach has come under criticism as dissatisfaction with sex assignment based on these criteria has been reported in several case studies ([Diamond and Sigmundson, 1997a](#); [Reiner, 1997](#); [Phornphutkul et al., 2000](#); [Hughes et al., 2007](#)). The importance of prenatal androgen imprinting has been implicated as an important variable in some of these cases ([Reiner, 1997](#)). Studies in undervirilized 46,XY males indicate that a small phallus can be associated with a satisfying adult sex life ([Reilly and Woodhouse, 1989](#)). Other studies have found that gender role tends to increasingly correspond with assigned sex as individuals with DSD proceed into adulthood ([Pappas et al., 2008](#)); therefore female sex assignment might not be necessarily warranted for intermediately undervirilized 46,XY males.

The degree of genital virilization is still an important determinant of sex assignment in the infant with ambiguous genitalia; however, other, incompletely understood factors appear to be involved. The formation of a healthy gender identity seems to involve a complex interplay between psychobiologic and environmental factors ([Money and Ehrhardt, 1972](#); [Meyer-Bahlburg et al., 1996](#); [Slijper et al., 1998](#); [Meyer-Bahlburg et al., 2006](#); [Singh et al., 2010](#)).

Embryology of Sex Determination and Differentiation

Normal and abnormal sex determination and differentiation constitute superb examples of how an understanding of embryology is critical to the approach and management of a group of complex

• BOX 97.1 Differential Diagnosis for Ambiguous Genitalia

46,XX Virilized Female

- Congenital adrenal hyperplasia
 - 21-Hydroxylase deficiency
 - 11-Hydroxylase deficiency
 - 3 β -Hydroxysteroid dehydrogenase deficiency
- Aromatase deficiency (fetal and maternal virilization)
- Virilizing maternal conditions
- Ovotesticular disorder of sex development
- Adrenal/ovarian tumors/luteoma of pregnancy
- Maternal ingestion of progestins, androgens

46,XY Undervirilized Male

- Androgen insensitivity
 - Partial
 - Complete
- 5 α -Reductase type 2 deficiency
- Testosterone biosynthetic defects
 - 17 β -Hydroxysteroid hydrogenase type 3 deficiency
 - 3 β -Hydroxysteroid dehydrogenase deficiency
 - 17 α -Hydroxylase/17,20-lyase deficiency
 - Congenital lipoid adrenal hyperplasia
- Leydig cell hypoplasia
- Idiopathic, undetermined
- Drug ingestion: progestins, spironolactone, cimetidine, phenytoin
- Persistent müllerian duct syndrome

Gonadal Differentiation and Chromosomal Disorders

- 46,XY gonadal dysgenesis
 - Complete (Swyer syndrome)
 - Partial
 - Mixed (45,X/46,XY)
- Ovotesticular disorder of sex development
 - 46,XX, 46,XY, 45X/46XY, 46,XX/46,XY

Syndromes Associated With Ambiguous Genitalia

- Gonadal dysgenesis
 - 46,XY partial gonadal dysgenesis (Turner syndrome features)
 - Camptomelic dysplasia
- Renal degenerative diseases and gonadal dysgenesis
 - Denys–Drash syndrome
 - Frasier syndrome
 - WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome
- Smith–Lemli–Opitz syndrome (7-dehydrocholesterol reductase deficiency)
- Robinow syndrome

and intriguing clinical disorders. Development of the testis and ovary is unique compared with the development of other organs in that they both derive from the same bipotential gonad. The establishment of a testis or an ovary depends on which pathway is taken on the basis of the genetic background. In the past the ovarian pathway was thought to be the default pathway. However, from studies of individuals with DSD, it is now known that ovarian development is an active process, and certain genes must be present for the ovary to develop.

Sex determination and differentiation are sequential processes that can be divided into three stages. Jost et al. (1970) established the sequence as follows: chromosomal sex is determined at fertilization and dictates the differentiation of the bipotential gonad, which in turn dictates the phenotypic sex, or the differentiation of the internal ductal system and external genitalia on the basis of which

hormones are produced by the gonad (Grumbach and Conte, 1998).

Chromosomal sex is determined at the moment of conception by the sex chromosome complement of the fertilizing sperm. If this sperm carries an X chromosome, a 46,XX (normal female) complement results. If the sex chromosome is Y, a 46,XY (normal male) genotype results. The *SRY* (sex-determining region of the Y chromosome) gene is necessary but not sufficient for testicular differentiation as other autosomal and X chromosomal genes are necessary for male sex development. *SRY* though is the only gene on the Y chromosome involved in testicular determination and differentiation. *SRY* through a number of steps instructs the medullary region of the bipotential gonad to develop into Sertoli cells and later into testicular cords and seminiferous tubules. *SRY* continues to be expressed at low levels in Sertoli cells until adulthood.

In addition to X chromosome genes, autosomal genes influence sex differentiation, insofar as mutations of these genes result in disorders of sex differentiation. Some of these genes include *WT1* (Wilms tumor gene 1), associated with Denys–Drash syndrome and WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome; *NR5A1* (nuclear receptor subfamily 5, group A, member 1), which encodes steroidogenic factor 1; and *SOX9*, which has been associated with camptomelic dysplasia and testicular dysgenesis in 75% of XY individuals (Foster et al., 1994). *SOX 9* expression is upregulated by *SRY*. The *DMRT1* and *DMRT3* genes on chromosome arm 9p when deleted are associated with female development in an XY individual. More recently, a de novo missense mutation in *DMRT1* was identified in a female with 46,XY karyotype, providing evidence that *DMRT1* is the critical gene for testicular differentiation (Murphy et al., 2015). The *FOXL2* gene is expressed in fetal and adult ovarian follicular cells and is critical to ovarian development, fertility, and maintenance of the ovary. It is also expressed in eyelids, with mutations leading to blepharophimosis–ptosis–epicanthus inversus syndrome, and is located within the homologous region in the human at 3q23 (Crisponi et al., 2001). The *DAX1* gene is located on Xp22 and appears to be necessary for correct testis determination and, in the mouse at least, necessary for the upregulation of *Sox9* expression (Bouma et al., 2005). When the *DAX1* gene is duplicated, 46,XY individuals develop gonadal dysgenesis with a female phenotype (Bardoni et al., 1994). The *WNT4* gene is critical for normal ovarian and female sexual development. A mutation in *WNT4* leads to müllerian duct regression and virilization in a 46,XX female (MacLaughlin and Donahoe, 2004), whereas duplication of the locus containing *WNT4* leads to overexpression of *DAX1* and thus a 46,XY female phenotype (Jordan et al., 2001). The desert hedgehog gene (*DHH*) is a member of a family of signaling genes with an important role in regulating morphogenesis. The follistatin gene (*Fst*) and the bone morphogenetic protein 2 gene (*Bmp2*) appear to be important for ovary organogenesis (Menke et al., 2003; Yao et al., 2004). Mutations in *Gata4* or *Fog2* can cause sex reversal in mice (Viger et al., 1998; Ketola et al., 2000; Tevosian et al., 2002). In humans, *GATA4* is a transcription factor necessary for genital ridge formation, testicular and ovarian differentiation, and male and female fertility. *GATA4* interacts with multiple genes, such as *SRY*, *SOX9*, and *AMH* as well as others involved in hormonal synthesis. *GATA4* acts synergistically with *NR5A1* to activate the *AMH* promoter, and a mutation in *GATA4* led to the lack of this synergy with *NR5A1* as well as inability for *FOG2* to bind to *GATA4*, resulting in familial 46,XY DSD and congenital heart defects (Lourenço et al., 2010). *FOG2* modifies

The diagram illustrates the genetic pathways for Ovary and Testis differentiation, branching from the **Genital ridge** and progressing over **TIME** from **Foetal** to **Adult** stages.

Ovary Pathway:

- Genital ridge** leads to **WNT4** and **RSPO1**, which activate β -catenin.
- β -catenin inhibits **SOX9**.
- NR5A1** (indicated with an orange arrow and a question mark) promotes **Steroidogenesis**.
- Steroidogenesis** leads to the formation of the **OVARY**.

Testis Pathway:

- Genital ridge** leads to **GATA4/FOG2/WT1**, which activates **SRY**.
- DMRT1** (indicated with an orange arrow and a question mark) also promotes **SRY**.
- NR5A1** (indicated with an orange arrow and a question mark) promotes **Sox8/SOX9**.
- FGF9** and **PTGDS** also promote **Sox8/SOX9**.
- NR5A1, GATA4, WT1, and SOX8** collectively promote **AMH**.
- SRY** promotes **DHH**, which leads to **Leydig cell** formation.
- Leydig cell** produces **NR5A1**, which promotes **Steroidogenesis**.
- Steroidogenesis** leads to the formation of the **TESTIS**.

Adult Stage and Mutual Inhibition:

- In the **Adult** stage, **DMRT1** (indicated with an orange arrow and a question mark) promotes **FOXL2** in the ovary.
- FOXL2** inhibits **SOX9** in the ovary.
- In the testis, **DMRT1** inhibits **FOXL2**, and **FOXL2** inhibits **SOX9**.
- A large orange double-headed arrow indicates a mutual inhibitory relationship between **SOX9** in the ovary and **FOXL2** in the testis.

GATA4 activity by binding to GATA4's zinc finger (Zaytouni et al., 2011). Missense mutations in *FOG2* have been identified in two individuals with 46,XY gonadal dysgenesis (Bashamboo et al., 2014). The current pathways to testicular and ovarian development are illustrated in Fig. 97.1.

Gonadal sex is established by 7 weeks' gestation. At this stage the fetus contains two internal ductal systems—wolffian and müllerian—and undifferentiated external genital primordia. The wolffian, or mesonephric, duct is a tubular structure that connects the capillary network of the mesonephros to the urogenital sinus. Evagination of the coelomic epithelium leads to formation of a second tubular structure adjacent to the mesonephric duct – the paramesonephric, or müllerian, duct. The distal ends of these two ducts are joined. That portion of the urogenital sinus distal to the

Phenotypic sexual differentiation is predicated on establishing gonadal sex. If an ovary develops, the wolffian ducts involute because of a lack of local testosterone exposure, and only the terminal portion persists as a Gartner duct. The müllerian ducts develop into the proximal portion of the vagina, uterus, and fallopian tubes (see [Fig. 97.2](#)). The unfused cephalic portions of the müllerian ducts form the fallopian tubes, whereas the caudal ends fuse to form the ureterovaginal canal (see [Fig. 97.2](#)). The union of the fused caudal ends of the müllerian ducts and urogenital sinus forms the vagina. The proximal two-thirds of the vagina is of müllerian duct origin, and the distal third is of urogenital sinus origin. There is no fusion of the labioscrotal folds and no increase in clitoral-phallic structure in the absence of elevated levels of circulating androgens.

Male phenotypic differentiation is the result of the elaboration of two distinct testicular hormones: testosterone and antimüllerian hormone (AMH). These factors are produced and secreted by the 8-week stage of development, and they are essential for normal male differentiation. Involution of the müllerian ducts is caused by AMH, which is a glycoprotein secreted by the fetal Sertoli cells. The remnants of the müllerian ducts persist caudally as the prostatic

• **Fig. 97.2** Embryologic timeline for gonadal development and development of internal and external genitalia. (From Larsen WJ. *Human Embryology*. New York, NY: Churchill Livingstone; 1993:237.)

utricle and cephalically as the appendix testis. AMH exerts its action unilaterally and locally (exocrine secretion) rather than bilaterally via the systemic circulation.

Immediately after müllerian duct regression, the wolffian ducts develop under the local influence of testosterone secreted by the fetal Leydig cells. The Leydig cells, like the Sertoli cells, differentiate from the mesenchymal cells within the gonadal ridges; this occurs at 9 to 10 weeks' gestation. Under the influence of testosterone, the wolffian ducts evolve into the epididymis, vas deferens, and seminal vesicles (see Fig. 97.2). The mesonephric tubules develop into the ductuli efferentes, which will provide continuity between the seminiferous tubules and rete testis to the vas deferens. This process occurs as a direct action of testosterone on the ductal structures.

Virilization of the male external genitalia, fusion of labioscrotal folds, and movement of the urethral opening, starts at approximately 8 weeks' gestation (see Fig. 97.2) and relies on the ability of the tissues involved to convert testosterone into a more potent androgen: dihydrotestosterone (DHT). The target cells possess the enzyme 5 α -reductase type 2, which is necessary for this conversion. By 12 to 14 weeks' gestation, formation of the male external genitalia is nearly complete. Androgen exposure after this time results in further phallic enlargement. Testicular descent occurs in two stages. The initial transabdominal descent occurs at 8 to 15 weeks and depends on insulin-like 3 and its G protein-coupled receptor. Other testicular factors likely also play a role as most dysgenetic gonads are intra-abdominal. Descent into the inguinoscrotal region occurs at 25 to 35 weeks and is androgen dependent.

Clinical Assessment of Differences of Sex Development

History

A detailed family history is important in the evaluation of ambiguous genitalia. Information on early neonatal deaths, consanguinity, or urogenital anomalies should be obtained. A family history of female infertility, amenorrhea, or müllerian duct abnormalities can be suggestive of a DSD. In one study of androgen insensitivity disorders that are X-linked, a positive family history of a sex differentiation disorder was often overlooked (Viner et al., 1977).

The presence of maternal virilization is suggestive of a variety of disorders that can affect fetal masculinization. Features of maternal virilization include hirsutism, severe acne, deepening of the voice, and clitoromegaly on examination.

The ingestion of any recreational drugs, alcohol, or medications by the mother during pregnancy should be noted. Particular attention to medications with androgenic or progestational activity is indicated. Medications that affect fetal genital development include cimetidine, spironolactone, hydantoin, and progestational agents (Grumbach and Conte, 1998). Progestational agents are used in assisted reproductive technology to support the pregnancy in the first trimester; therefore asking if the pregnancy was conceived spontaneously or through the use of assisted reproductive technology is important.

Physical Examination

There is significant overlap of the genital anatomy among the various sex differentiation disorders. The physical examination, however, can provide the first clues to the underlying disorder. In addition, the physical examination will provide important

information about the degree of virilization of the external genitalia and the presence or absence of palpable gonads. Prader stage (Fig. 97.3A) is used to describe the virilization of a female, and the external masculinization score (see Fig. 97.3B) developed by Ahmed et al. (2000) is used to describe the undervirilization of a male. The physical examination will also inform the examiner as to when the DSD occurred in fetal life.

Clitoris

Significant clitoral enlargement deserves careful evaluation. A point to keep in mind is that premature infants have relatively underdeveloped labia majora, so the clitoris may appear enlarged. A truly enlarged clitoris can be distinguished from a large clitoral hood by the presence of palpable corporal or erectile tissue.

Penis (Phallus)

Measurements of the phallic stretch length and middle shaft diameter are important in determining the degree of virilization. The phallus should be stretched and measured from the pubic ramus to the tip of the glans. Gestational age-corrected phallic stretch lengths are shown in Fig. 97.4. The presence of a chordee structure on the ventral surface of the phallus can impair measurement of the true phallic length (Feldman and Smith, 1975; Fig. 97.5). A chordee is residual urethral tissue that tethers the phallus to the perineum. Measurement of the middle shaft diameter is particularly useful in this circumstance. For term male infants, a normal middle shaft diameter is approximately 1 cm (Feldman and Smith, 1975).

A microphallus warrants careful evaluation for the presence of hypopituitarism or growth hormone deficiency, particularly in the presence of hypoglycemia or unexplained jaundice. Microphallus and undescended testes may occasionally be the presenting phenotype for a DSD.

Labioscrotal Folds

Assessment of the degree of fusion of the labioscrotal folds should be performed. When the infant is exposed to androgens during embryogenesis, fusion of the labioscrotal folds progresses from a posterior to an anterior direction. The spectrum of labial fusion can range from mild posterior fusion to complete labial fusion (Fig. 97.6). Fusion of the labioscrotal folds occurs in the first trimester. The examiner should note whether the folds are rugated or hyperpigmented. Is the phallus positioned in the normal superior position relative to the scrotum, or is there a shawl scrotum (penoscrotal transposition)? Is the scrotum fused normally in the midline or is the scrotum bifid (see Fig. 97.5)?

Gonads

Careful examination for the presence of gonads should be performed in all infants with ambiguous genitalia. The presence of bilateral gonads in the labial folds is highly suggestive of an undermasculinized genetic male (see Fig. 97.5). A unilaterally palpable gonad is often seen in infants with mixed gonad dysgenesis or ovotesticular DSD (Fig. 97.7), although other disorders such as androgen insensitivity can manifest themselves similarly. When cryptorchidism and hypospadias occur simultaneously, there is a greater than 25% chance of a DSD (Rajfer and Walsh, 1976; Albers et al., 1997).

Hypospadias, Perineum

The severity of hypospadias can differ, with the condition ranging from mild granular hypospadias to penoscrotal hypospadias (see

¹Microphallus is a phallic length below the male reference range.
²The location of the urethral meatus is based on the location described in C.

• **Fig. 97.6** Virilization of external genitalia in 46,XX congenital adrenal hyperplasia (21-hydroxylase deficiency). (A) There is a mild to moderate degree of virilization, with primarily clitoral hypertrophy and significant fusion of the labia. (B) Virilization is moderate, with clitoromegaly, labial fusion, and rugation of labial folds. (C–D) Complete masculinization is evident.

• **Fig. 97.7** Asymmetric external genitalia with left unilateral descended testis (A), penoscrotal hypospadias, and chordee (B). Asymmetric external genital development or gonadal descent would be characteristic of mixed gonadal dysgenesis or ovotesticular disorder of sexual development.

• **Fig. 97.8** Genitourethrogram. (A) Genitogram from a 46,XY infant with microphallus and undescended testes with a clearly delineated prostatic utricle (see [Case Study 2](#)). (B) Genitogram from a 46,XX infant with congenital adrenal hyperplasia and severe masculinization of external genitals. The confluence of the vagina with the urogenital sinus is of intermediate severity.

[Fig. 97.3C](#)), although most disorders of sexual differentiation manifest themselves with severe penoscrotal or scrotal hypospadias (see [Fig. 97.5](#)). Examination for the presence of separate urethral and vaginal openings versus a single perineal opening (urogenital sinus) conveys important anatomic information. The vagina may be blind ending or completely formed. A urogenital sinus results from failure of the urologic and genital tracts to differentiate completely. In virilized females the level at which the vagina enters the sinus (low-level versus high-level vaginal entry) has important implications for determining the ease of subsequent surgical exteriorization of the vagina ([Fig. 97.8](#)). In addition, when the urethra enters a urogenital sinus, there is potential for urinary stasis and therefore urinary tract infections. Excessive pigmentation of the genitals or signs of dehydration should alert the examiner to the possibility of congenital adrenal hyperplasia (CAH).

Dysmorphic features suggestive of Turner syndrome indicate the possibility of gonadal dysgenesis or mixed gonadal dysgenesis. Such abnormalities or multiple congenital anomalies could indicate any of a variety of syndromes associated with ambiguous genitalia ([Box 97.1](#)).

Radiologic Investigations

Pelvic Ultrasonography

Pelvic ultrasonography reveals vital information in the evaluation of DSDs. The presence or absence of a uterus is a critically important determinant in the initial evaluation ([Figs. 97.9–97.11](#)). The newborn period is a time when the uterus, ovaries, and adrenal glands are optimally visualized ([Wright et al., 1995](#)). The presence of a well-developed uterus will direct the differential diagnosis toward virilization of a genetic female, 46,XY ovotesticular DSD, 46,XY complete gonadal dysgenesis, or persistent müllerian duct syndrome (PMDS); however, a rudimentary uterus may be seen in 46,XY gonadal dysgenesis or ovotesticular DSD. The inability to identify a uterus though is not conclusive for lack of a uterus. Ultrasonography can locate undescended testes and determine gonadal size or irregularity, such as an oblong ovotestis. Gonads in the newborn are not always well visualized by ultrasound

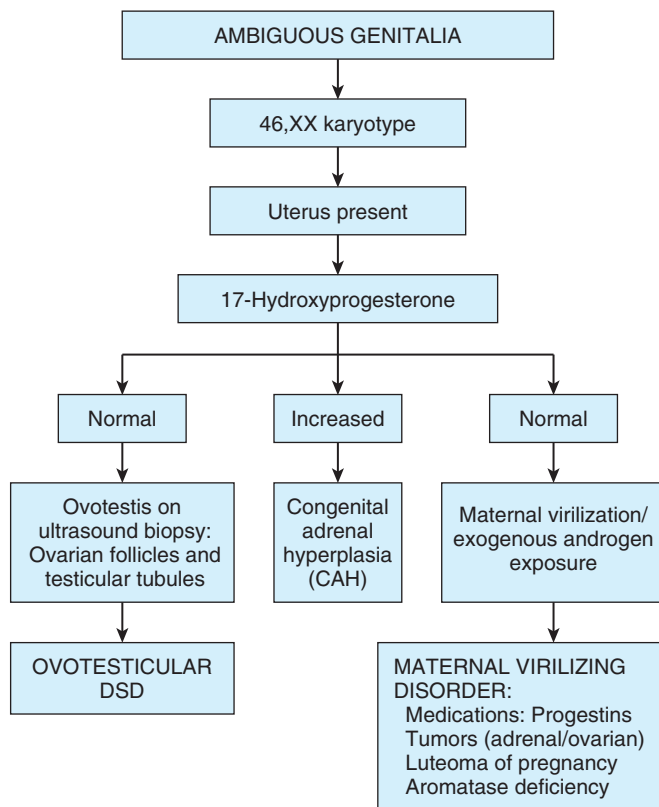

• **Fig. 97.9** Ultrasound image from a 46,XX infant with ambiguous genitalia. Note the presence of a well-developed uterus with an endometrial stripe.

examination, but that does not necessarily mean they are absent or abnormal. In ovotesticular DSD, loss of the uniform testicular echotexture suggests the presence of an ovotestis. Ultrasound examination can determine whether the adrenal glands appear enlarged, as in CAH; however, normal adrenal size does not rule out CAH.

Genitourethrogram

A genitourethrogram is a fluoroscopically guided genital dye study that can provide important information on the urethra and internal genital ducts ([Wright et al., 1995](#)). An experienced radiologist should perform this study. It is important to ensure that all perineal orifices are examined. The main features to be noted are the presence or absence of a vagina (or prostatic utricle) and the relationship between the vagina and the urethra (see [Fig. 97.8](#)). Demonstration of the level at which the vagina opens into the urogenital sinus and its relationship to the external sphincter has important surgical

• **Fig. 97.10** Algorithm for evaluation of the 46,XX infant with ambiguous genitalia. The presence of a uterus would be determined radiographically by ultrasound examination, genitourethrogram, or magnetic resonance imaging.

implications. Recognition of male or female urethral configurations may also be possible during genitourethrography.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been used to assess the internal genitalia of a limited number of infants and children with genital differentiation disorders. The strength of MRI lies in its ability to image large areas in multiple planes and characterize soft tissues. Detailed information about müllerian and wolffian structures and the position of the gonads can be obtained; however, thin sections (3 to 5 mm) are required for an adequate study. Streak gonads remain difficult to visualize. MRI has the capability to differentiate between an enlarged clitoris and a penis, because the bulbospongiosus muscle and transverse perineal muscle are absent or poorly visualized in the virilized female (Wright et al., 1995). MRI is a promising modality for the evaluation of ambiguous genitalia; however, further study is needed to demonstrate efficacy over other imaging modalities.

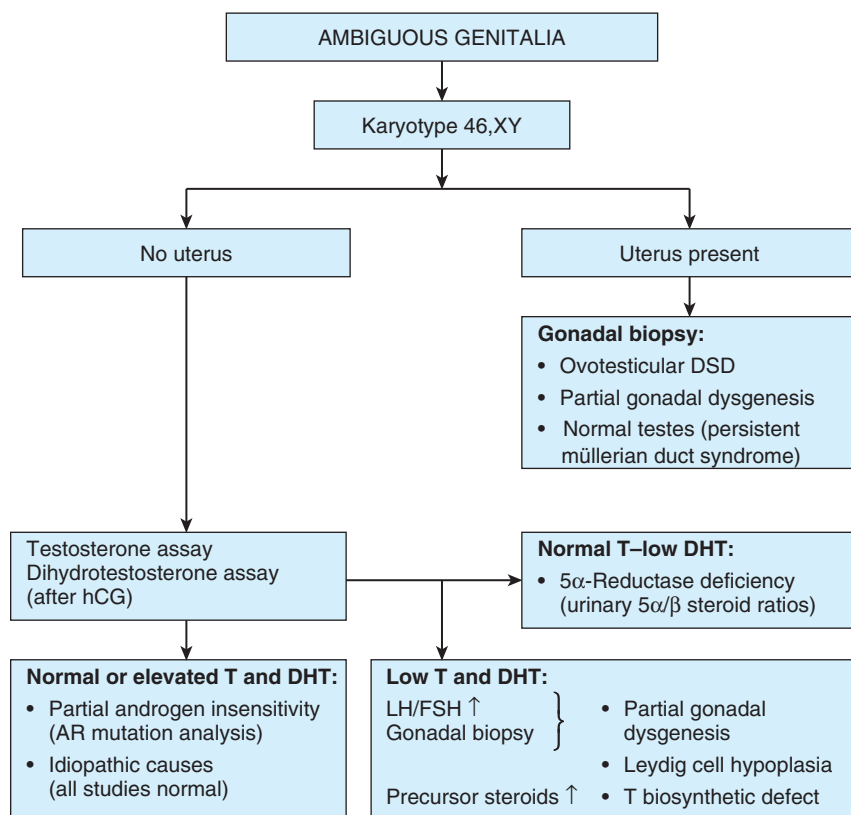

Laboratory Investigations

Endocrine and genetic laboratory studies are germane in the evaluation of ambiguous genitalia in the newborn. Day 1 of life is an ideal time to obtain serum testosterone and dihydrotestosterone (DHT) levels by liquid chromatography—tandem mass spectrometry (LC–MS/MS), as testosterone levels fall rapidly in the first several days of life (Forest et al., 1980). It is important to use LC–MS/MS assays as other assays measure interfering substances that will falsely elevate the testosterone level (Fuqua et al., 1995).

Chromosomal studies should optimally be performed on day 1, as a preliminary star karyotype with five cells can be available by 24 to 48 hours with use of the fetal nucleated red blood cells. Fluorescence in situ hybridization (FISH) for *SRY* should also be performed. On day 2 or day 3 of life, determinations of serum 17-hydroxyprogesterone (17-OHP), 17-hydroxypregnenolone, 11-deoxycortisol, dehydroepiandrosterone (DHEA), androstenedione, and plasma renin activity are performed if CAH is suspected. Some clinicians perform an adrenocorticotrophic hormone (ACTH) stimulation test at this time to more clearly demonstrate a block in steroid biosynthesis. Results of these studies should be sent immediately to the appropriate reference laboratory for analysis. Alerting the reference laboratory to the urgent nature of the studies performed will facilitate rapid processing. 17-OHP levels are physiologically elevated on the first day of life, and screening for CAH should preferably not be done at this time. Serum gonadotropins are often suppressed in the immediate newborn period, so they should be measured after 1 week of life. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels are helpful in assessing newborns for androgen insensitivity, gonadal dysgenesis, and LH receptor abnormalities. Repeated LH, FSH, testosterone, and DHT testing should be done between 2 and 8 weeks of life in the evaluation of undervirilized males. This period coincides with the physiologic testosterone surge (mini-puberty) seen in healthy male infants (Forest et al., 1980). When CAH is suggested, it is important to check sodium and potassium levels on a daily basis to prevent a salt-wasting crisis.

A human chorionic gonadotropin (hCG) test can be useful in the evaluation of suspected incomplete masculinization of the genetic male. However, if LH level is elevated, then hCG testing is not useful as it will not provide any additional information. hCG binds the LH receptor and stimulates the testes to synthesize sex steroids. A testosterone response greater than 200 ng/dL rules out a testosterone biosynthetic defect and is considered a normal response to hCG (a value less than 200 ng/dL may be normal in some assays). A normal testosterone-to-DHT ratio of less than 8:1 argues against 5 α -reductase type 2 deficiency, with the caveat that the testosterone level must be high enough to adequately test the enzyme function. The gold standard for 5 α -reductase type 2 deficiency is genetic testing as the testosterone-to-DHT ratio can be misleading. In addition, the hCG test can result in phallic enlargement if there is a good testosterone response. Almaguer et al. (1993) reported an increase in phallic length of 0.25 to 0.75 cm in six 46,XY males with idiopathic micropallus within 5 days of beginning injections. A bolus of 1500 international units (IU) of hCG was given intramuscularly on three consecutive days, with steroids and phallic length measured on the fifth day. Growth of the phallus in response to hCG suggests that the phallus will further virilize at puberty, although no longitudinal study has documented this assumption.

FISH can rapidly determine the sex chromosome complement of the newborn by use of X chromosome- and Y chromosome-specific centromeric probes (Schwartz et al., 1997; Fig. 97.12). In addition, this method allows the detection of low levels of chromosomal mosaicism, because hundreds of cells can be analyzed rapidly. FISH is also useful in identifying an *SRY* gene translocated to an X chromosome (Wang et al., 2009). FISH analysis for determination of sex chromosome constitution has been shown to be highly reliable, although this method has not been used extensively in the evaluation of ambiguous genitalia of the newborn. As a result, results should be interpreted with some degree of caution until confirmation by karyotypic analysis is available.

• **Fig. 97.11** Algorithm for evaluation of the infant with ambiguous genitalia and 46,XY karyotype. The presence or absence of a uterus would be determined by radiographic imaging, including ultrasound examination, genitourethrogram, or magnetic resonance imaging, as appropriate. Testosterone (T) and dihydrotestosterone (DHT) levels ideally should be obtained after human chorionic gonadotropin (hCG) stimulation or between 2 weeks and 3 months during the mini-puberty. AR, Androgen receptor; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

• **Fig. 97.12** Fluorescence in situ hybridization technique demonstrating the sex chromosome constitution of peripheral blood leukocytes. Arrows indicate sex chromosomes in each cell.

In a small percentage of ambiguous genitalia cases, laparoscopy with gonadal biopsy is necessary to confirm the diagnosis of ovotesticular DSD, gonadal dysgenesis, or Leydig cell aplasia. Obtaining a karyotype from gonadal tissue may be helpful when sex chromosome mosaicism is suggested.

46,XX Differences in Sex Development

Virilization of the Female

Virilization of an XX infant is most commonly caused by CAH, although other virilizing conditions can be involved (see Fig. 97.10). CAH encompasses a group of disorders of adrenal steroid hormone biosynthesis, of which more than 90% to 95% are due to 21-hydroxylase deficiency (OHD) (New, 1992; Fig. 97.13).

Occasionally, the presence of excess androgens of maternal origin can result in virilization of the female fetus (Grumbach and Conte, 1998). A unique cause of both maternal and fetal masculinization is placental aromatase deficiency (Conte et al., 1994). 46,XX testicular DSD, formally referred to as 46,XX maleness, can occur when the SRY gene is translocated from the Y chromosome to an X chromosome. Most patients with SRY-positive 46,XX testicular DSD have normal male external genitalia, but occasionally the genitalia are ambiguous (Fechner et al., 1993; Ergun-Longmire et al., 2005; Wang et al., 2009).

Congenital Adrenal Hyperplasia

21-OHD is the most common cause of ambiguous genitalia in the newborn female (New, 1992). It has a population frequency of approximately 1 in 15,000, and the disorder is inherited in an autosomal recessive fashion. Males and females are equally affected; however, in classic cases, females are virilized at birth, resulting in the clinical presentation of ambiguous genitalia.

Assessment for the less common forms of CAH resulting in ambiguous genitalia—11 β -OHD and 3 β -hydroxysteroid dehydrogenase (3 β -HSD) deficiency—includes measurement of 11-deoxycortisol, deoxycorticosterone (DOC), and 17-hydroxypregnenolone. Use of a comprehensive steroid panel from a reliable reference laboratory will limit the amount of blood required to 3 to 5 mL.

11 β -OHD accounts for approximately 5% of CAH cases worldwide, and this disorder will result in masculinization of the female fetus (see Fig. 97.13). However, the presence of volume overload and hypertension distinguishes this disorder from 21-OHD (New, 1992). Presumably the hypertension is caused by the excess mineralocorticoid activity of the DOC metabolite. Typically, 11-deoxycortisol level is elevated and plasma renin activity is suppressed in this disorder. However, hypertension may not present in the young infant, and thus absence of hypertension does not exclude 11 β -OHD.

3 β -HSD may result in ambiguous genitalia in the newborn period (see Fig. 97.13). Unlike 21-hydroxylase, this enzyme is present in the gonads as well as the adrenal glands, and deficiency of 3 β -HSD can result in undermasculinization of the male infant or mild masculinization of the female infant. 3 β -HSD is needed for testosterone biosynthesis; therefore the male fetus may be inadequately masculinized. This enzyme deficiency results in excess production of the steroid DHEA, which can be converted to more potent androgens peripherally. The female infant with this disorder can have clitoromegaly, although such children are often phenotypically normal. A marked increase in the ratios of 17-hydroxypregnenolone to 17-OHP and of DHEA to androstenedione is diagnostic in mutation-positive forms of this disorder (Sakkal-Alkaddour et al., 1996).

Treatment

Treatment of CAH in the newborn period consists of glucocorticoid and mineralocorticoid replacement. Hydrocortisone is the most physiologic form of synthetic glucocorticoids and is less likely to result in unwanted side effects. Hydrocortisone is administered orally initially at a dosage of approximately 25 mg/m² per day (divided into three doses) in the newborn period. No liquid preparation of hydrocortisone is currently available, so tablets must be crushed and administered carefully with formula or food. Mineralocorticoid replacement (fludrocortisone acetate [Florinef]) at a starting dose of 0.1 to 0.2 mg/d in the newborn is recommended but often needs to be increased. Sodium chloride supplements (approximately 1 to 2 g/d) are useful adjunctive therapy in salt-losing CAH, because formula and human milk have low salt contents. Once therapy has been initiated, careful monitoring of the infant's growth and determination of serum electrolytes, 17-OHP, androstenedione, testosterone, and plasma renin activity are recommended.

Salt-losing crisis and acute adrenal insufficiency should be treated with stress dosages of hydrocortisone (100 mg/m² per day), which can be given either continuously as a drip or divided into equal doses every 6 hours. Intravenous fluids with ample sodium chloride (normal saline for boluses and 0.5 N saline for maintenance fluids) are an essential component of treating salt-losing crisis. Care should be taken not to overhydrate or underhydrate the infant. Hyperkalemia often abates after sodium chloride and hydrocortisone are provided intravenously, although severe cases of hyperkalemia may require additional therapies.

Sex assignment for 46,XX infants with 21-OHD has traditionally been female (Donahoe, 1991; New, 1992; Migeon et al., 1994; American Academy of Pediatrics Committee on Genetics et al., 2000; Forest, 2001). Gender identity of 46,XX adults with CAH

is typically female, with various degrees of masculinized behavior (Money and Ehrhardt, 1972; Reiner, 1997). Prenatal androgenization affects gender-related behavior, but not gender identity, in girls with CAH aged 5 to 12 years (Meyer-Bahlburg et al., 2004a). Cases of gender identity disorder have been reported in treated females with CAH (Slijper et al., 1998), and cases of gender reassignment from female to male have been reported (Meyer-Bahlburg et al., 1996). Individuals with undiagnosed 46,XX CAH who are profoundly virilized have functioned successfully as males (Blizzard, 1999; Meyer-Bahlburg, 2009). Diamond and Sigmundson (1997b) suggested male sex assignment in profoundly virilized 46,XX individuals, although female sex assignment is likely to prevail in current practice until evidence is obtained to indicate otherwise (Lee, 2001; Crouch et al., 2008).

In addition to medical therapies for CAH, efforts to normalize the appearance of the external genitalia may be pursued. It should be kept in mind that hypertrophy of the clitoris will gradually lessen after medical therapy is instituted; however, complete normalization in the more virilized cases is not likely to occur. In severe cases of clitoral enlargement, clitoral recession surgery is a treatment option, although suboptimal cosmetic results have been reported in long-term outcome studies. Atrophy or loss of the clitoris or excessive regrowth of clitoral tissue has been described in examinations of adolescent and adult patients who underwent genital surgery in early childhood (Alizai et al., 1999; Creighton et al., 2001). If CAH is not well controlled with hormonal suppression of the adrenal gland, there will be clitoral enlargement. The risk of surgery needs to be balanced against the potential detrimental effects of masculinized genitalia on the development of a poor body image (Meyer-Bahlburg et al., 1996) and of social stigmatization by family or community members (Money et al., 1986). Nerve-sparing ventral clitoroplasty in virilized females has been shown to preserve dorsal nerves for better sensitivity after surgery (Poppas et al., 2007).

Surgical correction of the vagina in CAH is performed to exteriorize the vagina and to enlarge the vaginal opening so that successful intercourse can occur later in life (see [Overview of the Surgical Management of Disorders of Sexual Differentiation](#)). There is considerable debate about when to perform vaginal exteriorization surgery. A number of studies have demonstrated the development of vaginal stenosis when vaginoplasties are performed in the prepubertal period (Alizai et al., 1999; Krege et al., 2000; Creighton et al., 2001). The investigators advocate delaying vaginoplasty until puberty or later, when manual dilation can be undertaken by the patient, and estrogenization of the vaginal mucosa can help to prevent stricture formation. Others recommend that vaginoplasties be undertaken early in life, because the procedure is technically easier in the first several years of life, and the emotional trauma of a major surgery in adolescence is avoided (Donahoe, 1991; Schnitzer and Donahoe, 2001). Reports of long-term outcome of genitoplasty by patient advocate groups such as the Accord Alliance and others have called for a general moratorium on all nonessential genital surgery in infancy until affected individuals are old enough to express their wishes and give consent (Diamond and Sigmundson, 1997b). Problems with loss of sexual sensation and pleasure have been reported in adult patients as a consequence of genital surgery in early life. However, in cases of severe discordance between assigned sex and genital appearance, the psychosocial consequences of uncorrected genital anomalies can be damaging (Money and Ehrhardt, 1972; Money et al., 1986). Participation of the parents in the decision to pursue genital surgery after they have been fully informed of the benefits and risks is perhaps the most judicious

approach at this time (Reiner, 1997; Daaboul and Frader, 2001; Lee, 2001).

Significant reductions in fertility have been reported in women with salt-losing CAH (Mulaikal et al., 1987; Kuhnle et al., 1995). Suggested explanations for reduced fertility included increased anovulatory cycles, low rates of heterosexual activity, inadequate vaginal introitus, and poor adherence to medical treatment (Mulaikal et al., 1987). Problems with a disturbed body image and feeling less feminine were associated with a lower rate of success among women with CAH in terms of the ability to establish a partnership or marry (Kuhnle et al., 1995). Overall quality of life for female patients with CAH was comparable with that for controls, suggesting that affected women may develop coping strategies and cognitive appraisals that enable them to accept their life and view it as satisfying (Kuhnle et al., 1995).

CASE STUDY 1

History

- A 3.5-kg term infant born after an uncomplicated pregnancy.
- Cryptorchidism and hypospadias noted, with the infant discharged home as a male with a plan for outpatient surgical evaluation.
- Infant fed poorly at home, with intake of approximately 4 oz/day, no vomiting.
- On day 5 of life, notification of abnormal newborn screen for congenital adrenal hyperplasia by health department; referred to emergency department.

Evaluation

- On presentation to emergency department: infant was well appearing, weight 2.9 kg (representing a loss of 0.6 kg).
- Genital examination: 2.3 cm \times 1.1 cm phallus, severe hypospadias, marked labial fusion, no palpable gonads, marked hyperpigmentation of genitalia.
- Electrolytes: sodium 140 mEq/L, potassium 5.8 mEq/L, chloride 107 mEq/L, CO₂ 19 mEq/L, blood urea nitrogen 15 mg/dL, creatinine 1.0 mg/dL.
- Glucose 94 mg/dL.
- Ultrasound examination: uterus present, enlarged adrenals, no gonads seen.
- Karyotype 46,XX.
- 17-Hydroxyprogesterone 20,000 ng/dL (normal <200 ng/dL – unstimulated).
- Plasma renin activity 201 ng/mL per hour (normal <26 ng/mL per hour).

Management and Outcome

- Sex was reassigned female.
- Treatment with hydrocortisone (Cortef) and fludrocortisone acetate (Florinef) was started along with sodium chloride supplements.
- On day 10 of life, weight 3.2 kg, feeding 4 oz every 4 hours.
- By 4 months of age, significant reduction in clitoral and labial enlargement as well as resolution of hyperpigmentation.

Prenatal Diagnosis and Treatment

Diagnosis

Since the report by Jeffcoate et al. (1965) of the successful identification of an affected fetus by elevated concentrations of 17-ketosteroids and pregnanetriol in the amniotic fluid, investigators have performed prenatal diagnosis for CAH by measurements of hormone levels in pregnancy (Jeffcoate et al., 1965; New and Levine, 1973; Levine, 1986). The most specific hormonal diagnostic test for 21-OHD is elevated 17-OHP level in the amniotic fluid (Frasier et al., 1974;

Nagamani et al., 1978; Hughes and Laurence, 1979; Pang et al., 1980; Hughes and Laurence, 1982); Δ^4 -androstenedione level can be used as an adjunctive diagnostic assay (Pang et al., 1980). Amniotic fluid testosterone levels might not be outside the normal range in an affected male (Wilson et al., 1995). Measurement of hormone levels in amniotic fluid detects only severe cases, and for the most part it has been replaced by molecular diagnosis.

Molecular analysis of the 21-hydroxylase locus of amniotic fluid cells can make the diagnosis. It is important to know parental genotype so that the correct phase (*cis* versus *trans*) can be established. With the advent of chorionic villus sampling, evaluation of the at-risk fetus is currently possible in the first trimester at 10 to 12 weeks' gestation. The fetal DNA is used for specific amplification of the *CYP21A2* gene using polymerase chain reaction and Southern blotting, which has the advantage of requiring small amounts of DNA (Speiser et al., 1990). In the future, DNA analysis using cell-free DNA obtained from maternal blood may be possible. Because of improved accuracy and earlier diagnosis, molecular analysis of fetal DNA is now the method of choice for prenatal diagnosis. See Chapter 96 for more details.

Treatment

Treatment with dexamethasone can be used in pregnancies at risk of 21-OHD (Evans et al., 1985; Dorr et al., 1986; Speiser et al., 1990; Forest and David, 1991; Mercado et al., 1995) but is controversial and is still considered experimental. When properly administered, dexamethasone is effective in preventing ambiguous genitalia in the affected female. The current dose of dexamethasone is 20 μ g/kg divided into two or three doses daily (Mercado et al., 1995).

Adrenocortical steroidogenesis begins at approximately 6 weeks' gestation, and differentiation of the external genitalia and urogenital sinus begins at approximately 9 weeks' gestation (New et al., 1989). The institution of dexamethasone therapy is recommended as soon as pregnancy is confirmed and no later than 9 weeks after the last menstrual period; this will effectively suppress adrenal androgen production, allow normal separation of the vaginal and urethral orifices, and prevent clitoromegaly. The need to initiate therapy at such an early date means that treatment is blind to the sex of the fetus. If the fetus is determined to be a male on karyotyping or an unaffected female on DNA analysis, treatment is discontinued. Otherwise, treatment is continued to term.

Between 1978 and 2002, prenatal diagnosis and treatment of CAH caused by 21-OHD were performed in 595 pregnancies at the NewYork-Presbyterian Hospital-Weill Medical College of Cornell University, among which 108 infants had classic 21-OHD. Of these, 64 were females, 51 of whom were treated prenatally with dexamethasone. Dexamethasone administered at or before 9 weeks' gestation was effective in reducing virilization, thus avoiding postnatal genitoplasty (Carlson et al., 1999; New et al., 2001). No significant or enduring side effects were noted in the mothers (other than greater weight gain and a higher incidence of striae and edema than in untreated mothers) or the fetuses. There was no statistically significant difference in hypertension or gestational diabetes between treated and untreated mothers. All mothers who received partial or full treatment stated they would take dexamethasone again in the event of a future pregnancy. In this report and in others, no cases have been reported of cleft palate, placental degeneration, or fetal death, which have been observed in a rodent model of in utero exposure to high-dose glucocorticoids (Goldman et al., 1978; Nimkarn, 2005). In contrast, another study noted some significant maternal side effects, including excessive weight gain, cushingoid facial features, severe striae resulting in permanent

scarring, and hyperglycemic response to oral glucose administration (Pang et al., 1992).

A long-term follow-up study of 44 children treated prenatally in Scandinavia demonstrated normal prenatal and postnatal growth compared with matched controls (Lajic et al., 1998). Prenatally treated newborns also did not differ in weight, length, or head circumference from untreated, unaffected newborns (Carlson et al., 1999; New et al., 2001). Moreover, a survey of 174 children aged 1 month to 12 years and exposed prenatally to dexamethasone (including 48 with CAH) compared with 313 unexposed children (including 195 with CAH) found no differences in cognitive or motor development between the two groups (Meyer-Bahlburg et al., 2004b). Maria New believes proper prenatal treatment of fetuses at risk of CAH can be considered effective and safe. Long-term studies on the psychologic development of patients treated prenatally are currently under way. This therapy is controversial in other centers because of concerns of unknown long-term adverse effects and the fact that seven fetuses are treated for the benefit of one fetus. The current recommendations by the Endocrine Society and other societies are that dexamethasone therapy should be undertaken only as part of a controlled study with long-term outcomes (Speiser et al., 2010).

The efficacy of prenatal treatment in 11 β -OHD CAH has been shown as well. In 1999 Cerame et al. (1999) reported the first prenatal diagnosis and treatment of an affected female with 11 β -OHD CAH. As an indication of the treatment's success, the prenatally treated newborn had normal female external genitalia.

Increased Levels of Maternal Androgens and Progestins

Masculinization of the female fetus has been reported in pregnant mothers taking various progestational agents to prevent miscarriage. These agents include norethindrone, ethisterone, and medroxyprogesterone. Danazol, which has been used in the treatment of endometriosis, has been associated with fetal masculinization (Grumbach and Conte, 1998). Masculinization of the female fetus because of maternal virilizing ovarian or adrenal tumors or luteomas of pregnancy has been reported. In such cases, virilization beyond the time of birth does not occur, and the prognosis is good (Grumbach and Conte, 1998).

Placental Aromatase Deficiency

Placental aromatase deficiency has been associated with masculinization of the female fetus. Aromatase is a cytochrome P450 enzyme that is responsible for the conversion of testosterone to estradiol and of androstenedione to estrone. Autosomal recessive inheritance of aromatase deficiency causes virilization of the female because of a failure to metabolize the large amounts of androstenedione and testosterone produced by the placenta. This disorder also will cause significant virilization of the mother. The affected infant will be virilized, with normal müllerian structures. The levels of gonadotropins are elevated in infancy, and ovarian cysts may develop. At puberty, females have hypergonadotropic hypogonadism with failure to feminize and progressive virilization. Plasma androstenedione and testosterone levels are elevated, whereas estrone and estradiol levels are low. Postpubertal patients have delayed bone maturation, tall stature, and osteopenia (Conte et al., 1994).

46,XY Differences in Sex Development

Incomplete masculinization refers to absence of or incomplete masculinization of the external and internal genitalia in a person with a 46,XY karyotype and normal testes. Disorders leading to

incomplete masculinization of the male include androgen receptor defects, testosterone biosynthetic defects, 5 α -reductase deficiency, Leydig cell hypoplasia, and effects of maternal medications (see Fig. 97.11).

In 25%–50% of undermasculinized males, a specific cause cannot be found (Eil et al., 1984; Al-Agha et al., 2001; Baxter et al., 2015). Other factors such as medications and placental insufficiency may potentially interfere with genital masculinization. Placental insufficiency may be related to genital underdevelopment through the presumed mechanism of inadequate hCG production. Placental hCG is required for early fetal testosterone production and therefore early fetal genital development.

Medications such as cimetidine, spironolactone, phenytoin (Dilantin), phenobarbital, medroxyprogesterone, and cyproterone acetate have been associated with altered androgen action or metabolism. Their use during pregnancy may be detrimental to male genital development (Donahoe, 1991; Grumbach and Conte, 1998). Furthermore, various xenobiotics can bind the androgen receptor; therefore there has been speculation regarding the role of environmental factors in abnormal sex differentiation (Danzol, 1998).

Androgen Receptor Defects (Androgen Insensitivity)

Disorders of the androgen receptor are the most common definable cause of incomplete masculinization of the genetic male (Quigley et al., 1995). Disorders of the androgen receptor can be divided into complete androgen insensitivity syndrome (CAIS) and partial androgen insensitivity (PAIS) syndrome. The gene for the androgen receptor (*AR*) is located on the X chromosome, and more than 400 germline mutations have been found. Information regarding the *AR* mutations can be found in the McGill Androgen Receptor Gene Mutation Database (<http://www.androgendb.mcgill.ca>). Mutations have been found throughout the *AR* gene, with most mutations occurring in the DNA- or steroid-binding domains. Despite extensive characterization of the molecular genetics of *AR* mutations, no genotype–phenotype correlation has been found (Quigley et al., 1995).

The sex-differentiating actions of testosterone and DHT are mediated by the androgen receptor. DHT is important in the differentiation of the male external genitalia and prostate, whereas testosterone is important in the differentiation of internal wolffian ducts to epididymis, vas deferens, and seminal vesicles.

Complete Androgen Insensitivity

CAIS in a 46,XY individual is characterized by phenotypically normal female external genitalia (Fig. 97.14). Affected girls may have an inguinal hernia before puberty or primary amenorrhea after puberty onset. Robust breast development occurs at puberty that is due to peripheral aromatization of testosterone to estrogen. There is usually scant or absent pubic and axillary hair, with some vulvar hair. The vagina is short and blind ending, and müllerian structures (cervix, uterus, fallopian tubes) are absent because of testicular production of AMH. There are only vestigial or no wolffian duct–derived internal structures. The testes are located in the abdomen or inguinal canal or in the labia majora. Even though there is testosterone production at puberty, in the newborn there is absence of testosterone production during the mini puberty (Bouvattier et al., 2002). Gender identity and role behaviors are typically female. Removal of the testes is controversial because of low risk of development of germ cell tumors in childhood and

• **Fig. 97.14** (A) Appearance of external genitalia of a 46,XY infant with complete androgen insensitivity syndrome. (B) Note presence of bilateral palpable gonads.

during puberty (Hannema et al., 2006), and there is no consensus on the timing of orchidectomy (Migeon et al., 1994; Forest, 2001; Deans et al., 2012).

Partial Androgen Insensitivity

PAIS is characterized by various degrees of ambiguity of the external genitalia. The term *Reifenstein syndrome* was formerly used to describe partial androgen insensitivity with intermediate degrees of masculinization. Affected infants have a small phallus and a ventral chordee that tethers the phallus to the perineum. There is often a penoscrotal hypospadias and a bifid scrotum, which may or may not contain gonads (see Fig. 97.5). Cryptorchidism is a common finding. Müllerian structures are absent, and the wolffian duct-derived structures are absent or poorly developed. A genitourethrogram may demonstrate a urogenital sinus.

The diagnosis of partial androgen insensitivity is complex. A family history of ambiguous genitalia in male relatives on the maternal side would be suggestive of this diagnosis since it is X-linked. However, Viner et al. (1977) reported a family history in only 25% of patients with PAIS. 5α -Reductase deficiency and testosterone biosynthetic defects should be ruled out by appropriate steroid and/or genetic analysis. This can be accomplished by measurement of intermediates in testosterone biosynthesis, especially androstenedione, to exclude 17β -hydroxysteroid dehydrogenase (17β -HSD) type 3 deficiency and by measurement of the ratio of testosterone to DHT to exclude 5α -reductase deficiency. Abnormal testosterone-to-DHT ratios can be seen in PAIS (Ahmed et al., 1999); this could be caused by poor development of tissues, which express 5α -reductase type 2 in PAIS (Griffin et al., 2001). Genetic testing is the gold standard, and with the availability of DSD panels, sequencing in parallel rather than series is now possible.

Androgen levels in normal newborns are highest at birth and then decline rapidly during the first week. A second testosterone surge occurs between 15 and 60 days of life (Forest et al., 1980), which is often referred to as *mini puberty*. Androgen and LH levels should be obtained at these peak production times. Alternatively, an hCG stimulation test may be performed. There are many protocols for hCG stimulation testing. One hCG test is as follows: a dose of 3000 IU/m² of hCG is given intramuscularly daily for 3 days; androgen and gonadotropin levels are measured at the baseline and

then 24 hours after the third dose. Abnormally elevated levels of LH, testosterone, or both in the first several months of life are suggestive of partial androgen insensitivity. A recent report of five neonatal cases of PAIS showed testosterone values in the high-normal range on days 2 to 7 of life (mean 107 ± 27 ng/dL) and on day 30 (mean 411 ± 154 ng/dL; Bouvattier et al., 2002). LH levels were elevated in comparison with those of historic controls (mean LH level on days 7 to 15 of life was 5.2 IU/L ± 4.0 ng/dL; on day 30 of life the mean level was 8.7 IU/L ± 2.5 ng/dL). Testosterone response to hCG and LH response to gonadotropin-releasing hormone were exaggerated (Bouvattier et al., 2002).

The androgen receptor binding assay used to be considered standard for defining this disorder. However, normal ligand binding does not rule out androgen insensitivity, because there may be mutations in domains of the androgen receptor not involved in ligand binding. Direct sequencing of the androgen receptor for mutation analysis is commercially available (GeneTest) and can detect up to 95% of mutations associated with complete androgen insensitivity. Androgen receptor mutations, however, are not always found in cases of possible partial androgen insensitivity, and it is speculated that defects in androgen receptor-interacting proteins may be involved (Adachi et al., 2000) or the child may have another disorder. In the past, individuals were often labeled as having PAIS when in reality they had another disorder such as 17β -HSD deficiency. This has serious implications as at puberty this individual will virilize as other isoenzymes convert the androstenedione to testosterone.

Determining the sex of rearing in partial androgen insensitivity is a difficult task, and multiple factors must be considered. If there is a significant degree of virilization (Prader stages IV and V; see Fig. 97.3A), then male sex assignment is made (Diamond and Sigmundson, 1997b; Reiner, 1997). If masculinization is severely limited (Prader stages I and II), then female sex assignment is recommended. In intermediate forms (Prader stage III), responsiveness to exogenously administered hCG or testosterone may be of help in the decision-making process (Grumbach and Conte, 1998; Daaboul and Frader, 2001). However, adult males with a small phallus have reported satisfactory sex lives (Reilly and Woodhouse, 1989). These cases deemphasize the importance of phallic size in male sex assignment. Slijper et al. (1998) reported the absence of serious gender identity disorder in five undervirilized 46,XY males,

although these boys were “more fearful and bothered about the smallness of their penises.” Money and Ehrhardt (1972) cautioned about the devastating psychosocial effects of male sex assignment when the phallus is only slightly larger than a clitoris and does not respond to testosterone.

In a study of 32 undervirilized males who were assigned female gender for rearing, significant gender transposition (i.e., gender change and homosexual orientation) correlated with the presence of childhood stigmatization and a relatively late age at feminizing surgery (Money et al., 1986). Stigmatization in the home was reflected by the child being treated differently from other children, including elaborate efforts at maintaining the privacy of the genital anomaly, keeping the child at home and forbidding play with neighborhood children, and refusal of open communication within the family about the medical condition. Stigmatization in the community was reflected by teasing, such as about the genital anomaly, body habitus, and mannerisms. Stigmatization by parents or the community was also found to be associated with gender transposition in undervirilized males who were assigned male gender for rearing; cosmetic inadequacy of the external genitalia was less important (Money and Norman, 1987).

These studies indicate the importance of a nurturing, supportive environment for a successful long-term outcome for these children. More comprehensive long-term outcome studies of partial androgen insensitivity are greatly needed.

5 α -Reductase Type 2 Deficiency

5 α -Reductase type 2 deficiency is an autosomal recessive disorder that results in an inability to convert testosterone to DHT. DHT is required for the development of the male external genitalia.

At birth, these 46,XY infants typically have a very small phallus that appears to be a normal or slightly enlarged clitoris. However, more significant virilization of the phallus may occur, and the affected child will then be identified as a male with hypospadias. There is usually severe penoscrotal hypospadias. The scrotum is bifid, with slight posterior fusion. The testes are usually in the inguinal canals or labial folds. Approximately half of these patients have a penoscrotal urethra with a separate blind-ending vagina; a smaller percentage have a single urogenital sinus opening on the perineum (Griffin et al., 2001). A more recent study identified isolated microphallus (36%), microphallus with hypospadias (56%), and female external genitalia with clitoromegaly (9%) as the presenting phenotype (Cheng et al., 2015). Another study, of 55 patients with genetically confirmed 5 α -reductase type 2 deficiency, found the following phenotypes: clitoromegaly (49.1%), microphallus with hypospadias (32.7%), female external genitalia (7.35%), and isolated microphallus (3.6%) (Maimoun et al., 2011). Thus with the advent of genetic testing, the phenotypic range for 5 α -reductase type 2 deficiency is much broader than originally described. Müllerian structures are absent, and wolffian duct–derived structures (vas deferens, epididymis, seminal vesicles) are well developed. The prostate is poorly developed.

At the time of puberty, individuals with this disorder will characteristically virilize. The phallus will typically increase to a length of 4 to 8 cm (Migeon et al., 1994). In affected individuals who were raised as females, a change to the male gender role after puberty is commonly seen (Imperato-McGinley, 1997; Griffin et al., 2001). Unlike in partial androgen insensitivity, gynecomastia does not occur in the pubertal period.

In the past, 5 α -reductase type 2 deficiency was most often diagnosed in the postpubertal period, although diagnosis in the

newborn period has been reported (Imperato-McGinley et al., 1986; Odame et al., 1992). The disorder is diagnosed by assessment of the ratio of testosterone to DHT in blood (Peterson et al., 1977). The normal testosterone-to-DHT ratio in the newborn period is 4:1, whereas the ratio in infants and children with this disorder is often greater than 14:1. An hCG stimulation test is usually needed to obtain a more definitive diagnosis in the prepubertal period. A positive response to hCG rules out Leydig cell aplasia or a testosterone biosynthetic defect. Measurement of normal androstenedione levels will rule out the testosterone biosynthetic defect—deficiency of 17 β -HSD type 3. This enzyme is responsible for the conversion of androstenedione to testosterone in the testes, and the level of androstenedione is elevated compared with that of testosterone when 17 β -HSD deficiency is present. The clinical presentation of 17 β -HSD deficiency in infancy can be similar to that of 5 α -reductase deficiency or PAIS.

In addition, abnormal ratios of 5 β -urinary steroids to 5 α -urinary steroids can establish a definitive diagnosis of 5 α -reductase type 2 deficiency (Imperato-McGinley et al., 1986) but it can be challenging to perform the test. Distinguishing 5 α -reductase deficiency from partial androgen insensitivity is important because androgen insensitivity can cause a secondary DHT deficiency owing to the incomplete development of tissues that express 5 α -reductase activity (Griffin et al., 2001). Measurement of urinary 5 β -glucocorticoids and 5 α -glucocorticoids will help to make this distinction, because only 5 α -reductase deficiency will also affect glucocorticoid metabolism. Finally, analysis for mutations in the *SRD5A2* gene is diagnostic and is the gold standard. This gene test is available commercially as a separate test or as part of the DSD panel.

Sex assignment in cases of 5 α -reductase deficiency is a complicated issue, but long-term outcome information is available. As in androgen insensitivity disorders, sex assignment is often significantly influenced by the degree of masculinization at birth, and because infants with this disorder are usually markedly undervirilized, female sex assignment has been advocated (Migeon et al., 1994; Grumbach and Conte, 1998). However, if the disorder is diagnosed early, topical DHT treatment, which is not available in the United States, has been shown to enlarge the phallus (Odame et al., 1992). In addition, the natural history of the disorder is for masculinization of the phallus to occur at puberty. Testicular histopathologic analysis in males with this disorder has shown that, unlike in isolated bilateral cryptorchidism, their testes display type Ad (i.e., dark) spermatogonia and a normal germ cell count. These patients are largely infertile because of defective transformation of spermatogonia into spermatocytes (Hadziselimovic and Dessouky, 2008). However, there have been case reports of men fathering children (Katz et al., 1997; Kang et al., 2014). 46,XX females with 5 α -reductase deficiency do not have a known phenotype.

There are frequent reports of reversal from female to male gender behavior after puberty (Wilson et al., 1993; Wilson, 2001). The accumulated evidence supports male sex assignment in this disorder (Imperato-McGinley, 1997), although female sex assignment is likely in the newborn period if the diagnosis is overlooked.

Testosterone Biosynthetic Defects

Five enzymes are necessary for the synthesis of testosterone. A defect at any step will result in inadequate testosterone synthesis (see Fig. 97.13). Defects in the first three enzymes of the testosterone synthesis pathway will also affect adrenal steroid production, resulting in both an undervirilized male and CAH. Because

testosterone production is impaired in these disorders, wolffian duct structures are likely to be underdeveloped, whereas müllerian structures are absent because of normal testicular AMH production. These enzyme deficiencies are rare; therefore these disorders are discussed only briefly.

17 β -Hydroxysteroid Dehydrogenase Type 3 Deficiency (17-Ketosteroid Reductase Deficiency)

The final step in testosterone biosynthesis involves the conversion of androstenedione to testosterone by the enzyme 17 β -HSD type 3 in the testis. Mutations that impair the function of 17 β -HSD are the cause of this relatively rare autosomal recessive disorder (Wilson, 2001).

The clinical presentation externally is that of a female at birth with perhaps a mild degree of clitoral enlargement. The phenotype is female; therefore these infants are typically raised as females unless the diagnosis is made at birth. At puberty, there is progressive masculinization, with enlargement of the phallus to 4 to 6 cm, with labial enlargement and rugation. By late puberty, the testes are found at the lower ring of the inguinal canal, and they are of normal size and consistency. Internal wolffian duct–derived structures are found. In addition, a male body habitus develops, with deepening of the voice and appearance of male body hair, including a mustache and beard (Migeon et al., 1994).

In the past patients received a diagnosis at puberty or as adults. Now with the advent of genetic testing, this diagnosis is made more frequently in infancy. Endocrine studies reveal markedly elevated androstenedione levels, whereas testosterone levels are in the low-normal range (Mendonca et al., 2000). Plasma LH levels are consistently high. In infancy or childhood, the presence of inguinal hernias may bring the child to medical attention. Androstenedione levels in the prepubertal patient may be normal, and the hCG stimulation test is required to elucidate the defect outside the mini puberty.

Sex of rearing is often influenced by the cultural context. In societies in which a high priority is given to the male, sex reassignment at puberty has been successful (Forest, 2001). Mendonca et al. (2000) observed changes in gender role (female to male) in 3 of 10 affected individuals. Despite virilization in some affected individuals, the female gender role was maintained.

Congenital Lipoid Adrenal Hyperplasia

Lipid accumulation in both the adrenal glands and the gonads is characteristic of this disorder pathologically—hence the name *congenital lipoid adrenal hyperplasia*. Because all adrenal and gonadal steroid synthesis is affected by this disorder, infants are likely to exhibit complete adrenal insufficiency, characterized by vomiting, weight loss, and hypotension. The phenotype is likely to be female, although there is clinical variability. In the 35 cases reported in the medical literature, only 11 patients have survived beyond infancy (Forest, 2001).

Endocrine findings include elevation of ACTH level and plasma renin activity but low or immeasurable levels of all steroid hormones. The main consideration in the differential diagnosis is another form of CAH. The presence of markedly enlarged lipid-laden adrenals on ultrasound, computed tomography, or MRI studies is highly suggestive of the disorder. Successful treatment has occurred, and requires replacement of both glucocorticoids and mineralocorticoids. All individuals with this diagnosis have been raised as females (Grumbach and Conte, 1998).

In vitro studies performed on either adrenal or testicular tissue demonstrated an inability to convert cholesterol to pregnenolone

in these patients. A defect in the first step of adrenal and gonadal steroid biosynthesis mediated by the cytochrome P450 side-chain cleavage enzyme was suspected. However, subsequent molecular studies demonstrated mutations in the steroidogenic acute regulatory protein (StAR) (Grumbach and Conte, 1998). StAR acts to promote sterol translocation to the cytochrome P450 side-chain cleavage enzyme in mitochondria (see Fig. 97.13 and Case Study 2).

CASE STUDY 2

History

- The infant was born at 41 weeks' gestation, weighing 3.2 kg.
- Pregnancy was complicated by preterm contractions from 29 to 34 weeks requiring bed rest.
- Triple screen results were abnormal and amniocentesis was performed, revealing a 46,XY karyotype with no mosaicism. The parents did not want to know the karyotype because they did not wish to know the sex of the baby.
- At birth the newborn was thought to have normal female genitalia and was assigned to the female sex.
- On careful physical examination, the newborn was found to have mildly virilized genitalia.

Physical Examination and Laboratory Studies

- Genital examination: mild clitoromegaly, mild posterior labial fusion, a single urogenital sinus, and bilateral inguinal hernias with gonads present.
- Ultrasound examination: testicle-like structures in the upper portion of the inguinal canal without evidence of a uterus or ovaries.
- Karyotype and FISH: confirmed 46,XY, no mosaicism.
- Endocrine studies.

Six Weeks of Age

- Testosterone, 20 ng/dL; DHT, 11 ng/dL.
- FSH, 4.3 mIU/mL; LH, 9.0 mIU/mL.
- No mutations identified in the androgen receptor.

Three Months of Age

- Patient underwent a bilateral orchiectomy, inguinal hernia repair, and vaginoplasty.
- Testicular disease was consistent with prepubertal seminiferous tubules, spermatic cord with vas deferens, epididymis, and hernia sac.

Further Clinical Course: 6 Months of Age

- The patient had a 2-week history of irritability and several days of intermittent vomiting and was admitted to the hospital with dehydration and in adrenal crisis.
- Serum sodium level was 124 mEq/mL.
- Serum potassium level was 7.7 mEq/mL.
- There were low levels of all adrenal hormones, including testosterone, with no response to ACTH stimulation; baseline cortisol level was 10 μ g/dL, stimulated to only 12 μ g/dL 60 minutes after ACTH was administered.
- Plasma renin activity was 14,345 ng/dL per h.
- Baseline ACTH level was 4781 pg/mL.
- Genetic analysis revealed c. 178+1G>C intron 2 homozygous splicing mutation of the *STAR* gene.

Diagnosis

- Congenital lipoid adrenal hyperplasia owing to *STAR* mutation.

Management and Outcome

- Glucocorticoid supplementation with hydrocortisone and mineralocorticoid supplementation with fludrocortisone initiated.
- Female sex assignment maintained.

3 β -Hydroxysteroid Dehydrogenase Deficiency 2

3 β -HSD deficiency was first reported by Bongiovanni (1962). 3 β -HSD is an important enzyme required for the conversion of Δ^5 -steroids to Δ^4 -steroids in the adrenal glands and gonads (see Fig. 97.13). There is marked heterogeneity in clinical presentation, and both sexes are affected (Forest, 2001). With severe deficiency of 3 β -HSD, salt-losing crisis can occur. Male infants may have ambiguous or completely feminine external genitalia, whereas female infants may be mildly virilized. Severely undervirilized males may have normal mineralocorticoid activity; fully masculinized males may display salt loss.

Diagnosis of this disorder in the newborn period can be difficult because of relatively high levels of Δ^5 -steroids physiologically. The diagnosis is based on the elevated ratio of 17-hydroxypregnenolone to 17 OHP and of DHEA to androstenedione in the basal and stimulated states (Sakkal-Alkaddour et al., 1996).

17 α -Hydroxylase/17,20-Lyase Deficiency

A single enzyme encoded on the cytochrome P450c17gene (*CYP17A1*) mediates the 17-hydroxylation of pregnenolone and progesterone and the conversion of 17-hydroxypregnenolone and 17-OHP to DHEA and androstenedione. Specific mutations can cause partial loss of 17 α -hydroxylase/17,20-lyase activities or dissociation between the 17 α -hydroxylase and 17,20-lyase function (Dhir et al., 2009). Clinical disorders of this enzyme affect primarily either the hydroxylation or the lyase reaction, although there have been reports of combined 17 α -hydroxylase and 17,20-lyase deficiency (Sahakitrungruang et al., 2009). Cases of primarily 17-OHD should be considered in undervirilized males or females with low renin hypertension and hypokalemic alkalosis. The hypertension is presumably due to elevated levels of DOC and corticosterone (see Fig. 97.13). Most cases are diagnosed in the pubertal period because the 46,XY phenotype is largely female. Although cortisol synthesis is blocked, the overproduction of DOC and corticosterone is protective against adrenal insufficiency. This disorder is treated with glucocorticoid, which suppresses ACTH overproduction and subsequently suppresses DOC and corticosterone overproduction (Grumbach and Conte, 1998). Sex steroid replacement is needed at puberty.

17,20-Lyase deficiency results in various degrees of undermasculinization of the 46,XY infant. The phenotype ranges from complete female external genitalia to ambiguous genitalia to a mildly undervirilized male. 46,XX females will fail to enter puberty. The levels of gonadotropins will be elevated, and there will be impaired formation of DHEA and androstenedione (see Fig. 97.13). DOC and corticosterone levels are normal in this form of the disorder. ACTH and hCG stimulation tests may be helpful to more fully reveal the steroid biosynthetic block.

Leydig Cell Hypoplasia

Failure of the testes to produce testosterone in response to hCG is characteristic of this disorder. Histologic examination of the testes reveals absent or low numbers of Leydig cells, normal-appearing Sertoli cells, and seminiferous tubules with spermatogenic arrest (Grumbach and Conte, 1998). LH receptor mutations have been described in this disorder (Leung et al., 2006). Phenotypically, the external genitalia range from those of a normal female to those of a male with micropallus. Müllerian-derived structures are absent in all patients, whereas wolffian structures may be present. LH and FSH levels are elevated in postpubertal patients, and LH levels

decrease after testosterone administration. In less severe forms of the disorder, testosterone therapy augments phallic growth. In severe forms of testicular unresponsiveness to hCG/LH, sex assignment has been female. The gonads are removed, and estrogen replacement therapy is instituted at the time of expected puberty (Grumbach and Conte, 1998).

Persistent Müllerian Duct Syndrome

The diagnosis of PMDS is often made in otherwise phenotypically normal 46,XY males at the time of surgery for an inguinal hernia or orchidopexy. In the case of hernia repair, a fallopian tube and uterus are often found along with a partially descended testis. In other cases, testes, uterus, and fallopian tubes are found in the pelvis. Inheritance of PMDS is autosomal recessive, although the female phenotype is completely normal. The disorder has been found to be due to a mutation in AMH or its receptor in 85% of cases and unknown causes in 15% of cases (Josso et al., 2005). Therapy involves orchidopexy and partial hysterectomy, with care taken to avoid injuring the vas deferens, which is embedded in the uterine wall.

Gonadal Differentiation and Chromosomal Disorders

46,XY Complete Gonadal Dysgenesis

46,XY complete gonadal dysgenesis was first described by Swyer in 1955 (Grumbach and Conte, 1998). The phenotype of the external genitalia is female, with normal development of müllerian-derived internal structures in a 46,XY individual. The gonads did not develop into testes but rather formed streak gonads. Streak gonads are completely nonfunctional; they do not produce AMH or testosterone. Therefore müllerian structures do not regress, and wolffian structures are poorly developed or absent (Fig. 97.15). Most affected individuals are seen in the teenage years with lack of pubertal development. Serum gonadotropin levels are elevated. Mutations in the *SRY* gene account for only a small proportion of these cases (Forest, 2001). Fig. 97.1 depicts other genes that when mutated can lead to complete gonadal dysgenesis. Familial cases have been reported. There has been a report of a 46,XY mother who developed as a normal woman and gave birth to a 46,XY daughter with complete gonadal dysgenesis in a family with multiple disorders of sexual development, suggesting an unidentified sex-determining gene (Dumic et al., 2008). In up to 30% of affected individuals, gonadoblastomas will develop in the streak gonad; therefore removal of the streak gonad is recommended (Migeon et al., 1994; Looijenga et al., 2007; Pleskacova et al., 2010; see Fig. 97.15). Females with gonadoblastoma may present with breast development as the gonadoblastoma produces estrogen. Estrogen replacement therapy will provide appropriate feminization, and the subsequent addition of progesterone will lead to menses. Women with complete gonadal dysgenesis can successfully carry a pregnancy through the use of donor oocytes and appropriate hormonal supplementation.

46,XY Partial Gonadal Dysgenesis

Patients with 46,XY partial gonadal dysgenesis will typically be seen in the newborn period for evaluation of ambiguous genitalia (Berkovitz et al., 1991). The extent of masculinization of the external genitalia depends on the extent of testicular differentiation.

• **Fig. 97.15** (A) Appearance of external genitalia in an infant with 46,XY complete gonadal dysgenesis. (B) Uterus and fallopian tubes were found at surgery, along with a gonadoblastoma, at 1 year of age. (C) Micrograph of tumor cells.

Gonadal tissue is usually intra-abdominal, but testes can be found in the scrotum. One-quarter of these patients will have phenotypic features of Turner syndrome (Migeon et al., 1994). Testosterone response to hCG is variable but usually low. In most cases there is a mix of müllerian and wolffian structures. The presence of müllerian structures on genitourethrogram or ultrasound examination increases the index of suspicion for this disorder. The diagnosis is confirmed by gonadal biopsy. Some affected children are found to have one dysgenetic gonad on one side and a streak gonad on the other; others have bilateral dysgenetic gonads. Dysgenetic gonads are histologically defined by poorly formed and disorganized seminiferous tubules surrounded by wavy ovarian stroma. In many cases the dysgenetic gonads resemble ovotestes, except that primordial ovarian follicles are lacking (Berkovitz et al., 1991).

Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis refers to asymmetric gonadal dysgenesis with ambiguous genitalia (see Fig. 97.7) and a mosaic karyotype with an XY cell line. The most common karyotype is 45,X/46,XY. There is a wide spectrum of phenotypes, ranging from a female with clitoral enlargement to a male with hypospadias. Asymmetric external and internal genital development has been classically described in this syndrome (Forest, 2001). Considerable phallic development was reported in most patients in one study, and there was often penoscrotal hypospadias (Davidoff and Federman, 1973). The phenotypic features of Turner syndrome are described in a significant percentage of patients, although these features may not be readily apparent in the newborn period. An incompletely formed uterus is found in almost all patients. Fallopian tubes are always found on the side of the streak gonad and often on the side with the dysgenetic gonad. Wolffian structures may be developed on the side with the dysgenetic gonad.

A genitourethrogram is likely to demonstrate internal müllerian structures that can be confirmed at laparoscopy. Demonstration of abnormal gonadal histopathologic features will confirm the diagnosis. Mixed gonadal dysgenesis shares many features with partial gonadal dysgenesis, and some authors view these disorders as representing a continuum of gonadal dysgenesis (Berkovitz et al., 1991). Histologic analysis will also differentiate this disorder from ovotesticular DSD. Although the characteristic karyotype is 45,X/46,XY, this genotype has been associated with normal male differentiation in most cases diagnosed by prenatal amniocentesis (Wheeler et al., 1988). While these males may have normal external genitalia, they may also have short stature and cardiac features associated with Turner syndrome.

Some authors advocate female sex assignment in mixed gonadal dysgenesis, because surgical repair of the vagina is usually easy and a uterus or hemiuterus is present. In addition, the dysgenetic gonad is at risk of development of a tumor and should be removed, particularly if the gonad cannot be brought down into the scrotum (Forest, 2001). However, sex assignment is likely to be guided by the degree of virilization, with the more virilized cases being assigned as males. The capacity for near-normal androgen production in this disorder has been described (Davidoff and Federman, 1973). In all cases the streak gonads should be removed because of the risk of malignancy.

Testicular Regression Syndrome

Testicular regression syndrome refers to the spectrum of disorders affecting individuals with 46,XY karyotype who demonstrate evidence of prior testicular function, followed by usually symmetric gonadal regression (Marcantonio et al., 1994). Loss of testicular function between weeks 8 and 10 of gestation would result in ambiguous genitalia and variable internal genitalia. Loss of testicular function after 12 to 14 weeks' gestation would result in normal

male genital differentiation with a small phallus. When the male external and internal ducts are completely normal, the term *vanishing testis syndrome* is used by some authors. Presumably the testes were lost during the second half of pregnancy. Testicular torsion or loss of blood supply has been invoked as a possible explanation in this syndrome.

FSH levels are elevated in infancy, and an exaggerated response to gonadotropin-releasing hormone in the prepubertal period is typically seen (Grumbach and Conte, 1998). AMH levels in infancy and childhood are very low in anorchia and intermediately low with abnormal testes (Lee, 2001).

Ovotesticular Disorder of Sex Differentiation

Ovotesticular DSD is defined as the presence of both testicular tissue with distinct seminiferous tubules and ovarian tissue containing mature graafian follicles in a single individual. Both testicular and ovarian elements may be found in the same gonad, or one testis and one ovary may be found in the same individual. In most cases the karyotype is 46,XX; 46,XX/46,XY chimerism and 46,XY karyotypes can also be found. Clinically the external genitalia are often ambiguous, but predominantly male or female phenotypes have been described (Hadjiathanasiou et al., 1994; Grumbach and Conte, 1998). In ambiguous cases a relatively marked degree of virilization can be found. Almost all have some degree of hypospadias and incomplete labioscrotal fold fusion. The labioscrotal folds are asymmetric, with an appearance of a hemiscrotum on one side and labium majus on the other being seen in 10 of 22 cases (Hadjiathanasiou et al., 1994). At least one gonad is usually palpable. A vagina and a uterus are present in most patients, and a genitourethrogram may provide further elucidation. Internal duct development is consistent with the associated gonad, although müllerian ducts predominate with an ovotestis. Breast development is common during puberty, and menses can occur in up to 50% of individuals.

The diagnosis should be suggested in 46,XX/46,XY individuals with ambiguous genitalia. Palpation of a polarized gonad should also lead the clinician to suggest the diagnosis. In one study, 11 of 12 individuals with 46,XX ovotesticular DSD examined before 6 months of age had baseline testosterone levels greater than 40 ng/dL; normal levels for females of this age would be less than 15 ng/dL (Hadjiathanasiou et al., 1994).

Sex assignment depends on the degree of masculinization, the capacity of testicular tissue to secrete testosterone, and the presence or absence of a uterus and tubes. In general, a female sex assignment is favored because of the presence of ovarian tissue and external genitalia that can more easily be reconstructed as female. Male sex assignment is more likely if there is significant virilization. Removal of ductal or gonadal structures not consonant with the sex of rearing is controversial as gender identity is not known in infancy. Testes are usually dysgenetic, which carries an increased risk of gonadoblastoma formation; therefore careful follow-up evaluation is indicated. As in all cases of DSD, gender identity and behavior issues, along with general psychologic well-being, should be evaluated longitudinally.

Syndromes Associated With Ambiguous Genitalia

Denys–Drash syndrome is a rare syndrome consisting of the classic triad of congenital nephrotic syndrome leading to end-stage

renal failure, XY ambiguous genitalia, and Wilms tumor. The external genitalia of 46,XY individuals are either ambiguous or female. Gonadal development encompasses a spectrum from streak gonads to dysgenetic testes. Nephropathy and proteinuria are noted at an early age, and renal biopsy will demonstrate mesangial sclerosis. More than 90% of cases will have a mutation in the *WT1* gene, which is a critical gene for the development of the normal genital tract. *WT1* is also associated with WAGR (Wilms tumor, aniridia, genitourinary anomalies, retardation) syndrome. Large deletions of chromosome band 11p13 that encompass the *WT1* gene are responsible for this disorder. Frasier syndrome also involves the *WT1* gene. This syndrome manifests itself in 46,XY females with gonadal dysgenesis and progressive glomerulopathy. The risk of gonadal malignancy in Frasier syndrome is reported as 60% and in Denys–Drash with a Y chromosome as 40% (Looijenga et al., 2007).

Camptomelic dysplasia is a rare autosomal dominant disorder associated with often lethal skeletal dysplasia, in which 75% of affected 46,XY males have dysgenetic testes associated with undervirilization (Foster et al., 1994). Manifestations of this disorder include bowing of the femora and tibiae, hypoplastic scapulae, 11 rib pairs, pelvic malformations, bilateral clubfoot, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. The disorder is caused by heterozygous mutations in the *SOX9* gene (Wagner et al., 1994). Most patients die of respiratory distress in the neonatal period.

Smith–Lemli–Opitz syndrome is an autosomal recessive disorder with an estimated frequency of 1 in 20,000 to 1 in 40,000. The disorder is caused by deficiency of 7-dehydrocholesterol reductase (Forest, 2001). This enzyme catalyzes the final step in cholesterol biosynthesis; therefore the combination of low serum cholesterol level and a high serum 7-dehydrocholesterol level is suggestive of the diagnosis. Growth and severe developmental delay and multiple congenital anomalies characterize this disorder. Genital anomalies may include hypospadias, cryptorchidism, micropenis, and hypoplastic scrotum. Craniofacial abnormalities may include microcephaly, narrow bifrontal diameter, broad maxillary ridges, ptosis of the eyelids, micrognathia, and anteverted nostrils (Jones, 1997). Syndactyly of the second or third toes is a common feature. Adrenal insufficiency has been reported in this condition. Treatment with cholesterol has been used to try to improve growth and neurodevelopmental status. Unfortunately cholesterol replacement has not been as beneficial as once hoped as it does not cross the blood–brain barrier and has not been shown to reduce developmental delay (Sikora et al., 2004). A more recent placebo-controlled trial using simvastatin (non–FDA-approved indication) found that the medication crossed the blood–brain barrier and was relatively safe. There was improvement in serum dehydrocholesterol-to-total sterol ratio and improvement of irritability symptoms (Wassif et al., 2017).

Robinow syndrome is an autosomal dominant disorder characterized by a flat facial profile, short forearms, and hypoplastic genitals (Jones, 1997). Sporadic cases have been reported. Microphallus may be severe in males, although normal virilization at the time of puberty has been reported (Jones, 1997). Undescended testes have been reported in 65% of affected boys. Females have characteristic hypoplastic labia and clitoris. Other features include small size at birth, macrocephaly, frontal bossing, hypertelorism, prominent eyes, small upturned nose, micrognathia, and posteriorly rotated ears. Short forearms are seen in 100% of described cases. Other skeletal abnormalities include thoracic hemivertebrae, fusion or absence of ribs, and scoliosis. The abnormal facial features become

less pronounced as the child grows, and cognitive performance has been normal in most affected individuals.

Other Disorders of Genital Differentiation

Hypospadias is one of the most common anomalies of male genital development, with an estimated incidence of 4 to 8 cases per 1000 male births (Grumbach and Conte, 1998). Hypospadias can be classified as glanular, subcoronal, distal penile, midshaft, proximal penile, penoscrotal, scrotal, and perineal (see Fig. 97.3C). Typically, the more severe forms of hypospadias have been associated with DSD, although the phenotypic spectrum of DSD is wide. In a study of 33 patients with severe (scrotal or penoscrotal) hypospadias, 12 were found to have a DSD, which included Denys–Drash syndrome (in 3 of the 12), partial androgen insensitivity (in 2), ovotesticular DSD (in 2), chromosomal abnormality (in 1), AMH abnormality (in 1), gonadal dysgenesis (in 1), 5 α -reductase deficiency (in 1), and 46,XX *SRY*-positive karyotype (in 1) (Albers et al., 1997). The testes were undescended in 11 of the 12 patients. Aarskog (1970) found an approximately 15% prevalence of DSD in association with hypospadias, in addition to a significant role for maternal progestins. Intrauterine growth retardation and prematurity also have a higher association with hypospadias and undescended testes thought to be due to placental insufficiency, with lower hCG levels leading to decreased androgen production early in the pregnancy (Sekaran et al., 2013).

Thus severe cases of hypospadias require a thorough evaluation, including karyotype and evaluation of testosterone biosynthesis, along with examination of the genitourinary tract, particularly if accompanied by undescended testes.

Overview of the Surgical Management of Disorders of Sexual Differentiation

Surgery for DSD conditions has been criticized recently. The criticism has focused not only on the timing of surgery but also on whether reconstructive surgery should be done at all. Some authorities have advised that surgery be postponed until the affected person is of an age to make his or her own decision regarding the advisability of surgical correction (Diamond and Sigmundson, 1997b). Others have found that delay in surgery may be associated with problematic outcomes (Money et al., 1986; Meyer-Bahlburg et al., 1996; Reiner, 1997). It is imperative that these divergent viewpoints be discussed with the parents of an infant with a DSD condition.

These issues must be kept in mind in any decision regarding surgery for management of DSD. Current surgical techniques that are available for correction of ambiguous genitalia and DSD are presented next.

Feminizing Genitoplasty

Feminizing genitoplasty is one of the more common procedures done for correction of ambiguous genitalia. Feminizing genitoplasty is indicated in the genetic female who is externally virilized, most commonly as the result of CAH. The degree of virilization can be highly variable (see Fig. 97.6) and will have a significant influence on the type of procedure done, especially the vaginoplasty portion of the operation. Reconstruction in this group of patients has three components: clitoral reduction, vaginoplasty, and labial reconstruction. The timing of surgical correction also has undergone some

changes over the years. The current thinking is that once a decision is made to proceed with genital reconstruction, performance of this type of surgery at a younger age will have distinct advantages, including easier mobilization of the urogenital sinus and a more benign postoperative course.

Clitoral Reduction

Attempts at managing the enlarged clitoris in genetic females with clitoral hypertrophy started with total clitorectomy. Young (1937) originally advocated this procedure. Later, Lattimer (1961) suggested a recession rather than a resection of the clitoris, and he hoped to be able to preserve the arousal function of the clitoris. This led to cases in which painful clitoral erections occurred later in life; therefore further modification was needed. Spence and Allen (1973) advocated the preservation of the glans with reduction in the size of the clitoris. Since then, several reports have examined preservation of the neurovascular bundle using a clitoral reduction and recession type of approach. Kogan et al. (1987) and Snyder et al. (1983) separately described a similar approach in which the erectile tissue of the clitoris is removed, but preservation of the neurovascular bundle and the glands is afforded to preserve the neurologic and arousal functions of the clitoris. If the glans is unusually large, then a reduction of the glans size may be indicated as well.

Vaginoplasty

Reconstruction of the vagina in cases of virilization in females requires an understanding of the anatomy. One may consider the anatomic abnormality an embryologic arrest of maturation with a persistence of an early embryologic stage. The anatomic issue that is important to the surgical management of the common urogenital sinus is the site of confluence of the genital tract and urethra. This site varies considerably but is somewhat predictable from the appearance of the degree of external virilization. Children with severe degrees of external virilization are more likely to have a higher confluence of the urethral and vaginal channels, leading to a longer urogenital sinus or a more masculinized urogenital sinus. In the classic article on urogenital sinus abnormalities, Hendren and Crawford (1969) described the variable anatomy that can be seen in these children and noted that the operative procedures needed to be tailored toward the location of the confluence of the urinary and genital tracts. One may describe the confluence anatomically as it relates to the external sphincter, with confluences distal to the external sphincter being considered *low* and those proximal to the external sphincter being referred to as *high*. One also may describe the variable anatomy according to the length of the urethra from the bladder neck to the point of confluence. If that length of urethra were long, then one would consider this a low confluence. Conversely, if the length of the urethra were short and therefore close to the bladder neck, then a high confluence would be present (see Fig. 97.8B).

The low confluence cases can generally be repaired either by a cutback procedure on the fused labioscrotal folds or by a flap vaginoplasty. A cutback procedure would be indicated in cases with a minor degree of fusion of the labioscrotal folds. The middle to high vaginal confluence, however, generally requires either a pull-through vaginoplasty or a total urogenital mobilization to bring the vagina down to the perineum.

Flap Vaginoplasty

Flap vaginoplasty should be used for a low confluence of the urogenital sinus. The procedure entails mobilization of a

perineum-based flap with its apex at the meatus of the urogenital sinus. Dissection then proceeds along the posterior wall of the urogenital sinus until the vaginal opening is identified. The perineum-based flap is then inserted into the posterior wall of the vagina, thereby exteriorizing the vagina to the perineum.

Total Urethral Mobilization

Total urogenital mobilization can be used for the high urogenital sinus, which has been advocated by [Pena \(1997\)](#) and subsequently substantiated by a report from [Rink et al. \(1997\)](#). This approach has been shown to have a superior cosmetic result, compared with that obtained with a flap vaginoplasty, for a middle to high confluence. In addition, there has been a reduced incidence of urethral vaginal fistula and vaginal stenosis. The mobilization occurs in a plane both anterior to the urogenital sinus and up to the bladder neck under the pubic symphysis and posteriorly along the urogenital sinus, and then along the posterior wall of the vagina.

Pull-Through Vaginoplasty

Pull-through vaginoplasty is reserved for use in severely masculinized genetic females, whose surgical treatment continues to present a major challenge. Initially, the approach was a combined perineal and abdominal approach with complete mobilization of the vagina and uterus and separation of the vagina from the urethra at the confluence. The abdominal mobilization will then allow the vagina to be brought down to the perineum. A modification of this approach was described by [Passerini-Glazet \(1989\)](#) in which the more distal urogenital sinus tissue was used to provide an anterior vaginal wall flap, which will then connect to the true vagina and allow a complete perineal approach to the procedure.

Vaginal Agenesis

Vaginal replacement has a role in certain DSD or structural abnormalities of the genital urinary tract. The DSD in which vaginal replacement may be indicated are 46,XX vaginal agenesis, 46,XY male karyotype with severely inadequate virilization or CAIS, and structural urogenital defects such as cloacal exstrophy or persistent cloaca or after a pelvic exenteration for malignancy. A variety of tissues and techniques are used for vaginal reconstruction: skin grafting, progressive perineal indentation, and split-thickness or fold thickness tissue grafts with expanders, myocutaneous flaps, and bowel segment. The critical point in creating a vagina is to maintain an adequate perineal opening, an adequate-length tunnel, and good fixation to pelvic structures. This area is highly controversial in terms of the best management. Overall, the most popular tissue for vaginal plate replacement has been the split-thickness skin graft as described by [McIndoe \(1950\)](#). The major disadvantage of this technique has proved to be the need for long-term dilatation to maintain patency and to avoid vaginal stenosis. Recently, buccal mucosa grafts have been used rather than skin grafts for vaginal replacement as an alternative to the McIndoe graft. The use of bowel segments for vaginal replacement was first described by [Baldwin \(1904\)](#). Because of an extraordinarily high mortality rate associated with this approach, earlier attempts using this technique were abandoned. Since then, this approach has been adopted by many groups and has been shown to be highly successful, with minimal complication rates. Early on, intestinal mucus production can be a problem, but this lessens over time, and mucus may act as a natural lubricant. Minimal perineal scarring is associated with this approach as well, and it can be done at a very young age ([Hensle and Dean, 1992](#)). Because of the risks and complications with any surgical approach, vaginal dilation has

been recommended, when feasible, as first-line therapy for patients with vaginal agenesis who are candidates for a nonsurgical approach.

Undervirilized Males

Inadequate virilization results in hypospadias with or without cryptorchidism. In more severe cases, such as a complete form of androgen insensitivity, these children may appear as phenotypically normal females and present at the time of puberty with primary amenorrhea. Vaginoplasty is frequently needed after puberty in that population if vaginal dilation is unsuccessful. Children with varying degrees of hypospadias, with or without cryptorchidism, will usually require a repair following the usual principles of hypospadias and cryptorchidism repair. These repairs are generally done at 6 months of age and are tolerated well as outpatient procedures.

Gonadectomy

Gonadectomy is considered under two circumstances in DSD: when the assigned sex is different from the gonadal sex, mostly in the 46,XY DSD and 45,X/46,XY DSD, and when there is a risk of tumor related to the testicular tissue. This is most commonly seen in androgen insensitivity syndrome (46,XY karyotype) in which normal testes are present but a female sex assignment has been made. Conservative management of the gonads in CAIS until puberty is recommended, since tumors in these gonads do not develop until puberty and the risk is less than 1%. Alternatives to gonadectomy include bringing the gonads down (orchiopexy), monitoring with clinical examinations, imaging studies, and biopsies, although there are limited data regarding safe and effective long-term surveillance. In DSD where there is a risk of virilization at puberty, hormonal suppression may be an alternative to surgical management until the patient is able to consent. Gonadal malignancy is a significant risk in DSD in which dysgenetic gonads and a Y chromosome are present. An example is shown in [Fig. 97.15](#), in which a 1-year-old infant with complete XY gonadal dysgenesis was found to have a gonadoblastoma on gonadectomy. Other syndromes in which gonadal malignancy is a concern include mixed gonadal dysgenesis and the presence of a dysplastic testis in a dysgenetic XY male.

Removal of Müllerian Remnants

Removal of müllerian remnants in male-assigned patients is not recommended unless they are associated with symptoms, such as dysuria, urinary tract infections, pain, bleeding, herniation, and stone formation. Removal of the müllerian remnant can be performed laparoscopically. In most cases, müllerian remnants are asymptomatic, and cancers have rarely been reported ([Josso et al., 2005](#); [Farikullah et al., 2012](#)).

Conclusions

Significant advances have been made in our understanding of the pathophysiology and molecular genetics of DSD. A systematic diagnostic approach to the infant with ambiguous genitalia should be undertaken to identify the underlying disorder. Establishment of the diagnosis will provide a better understanding of the natural history of the disorder and enable better counseling of the family. Decisions regarding sex of rearing, need and urgency for gonadectomy, and recurrence risk are also enhanced if a specific diagnosis can be made.

CASE STUDY 3

History

- A 3-week-old 46,XY male infant with penoscrotal hypospadias presented with history of weight loss during the previous 2 weeks. He had a normal cortisol level of 50 µg/dL after ACTH stimulation testing at 1 week of age.
- The infant had decreased breastfeeding and had taken only 2 oz by bottle during the previous 24 hours.
- No emesis. No lethargy. No fever.

Evaluation

- On presentation to the emergency department the infant had a loss of 0.4 kg since his visit to the DSD clinic 2 weeks previously.
- Genital examination: 3 cm × 1.2 cm phallus, severe chordee, penile scrotal hypospadias, bilateral nonpalpable gonads, and bifid scrotum.
- Electrolytes: sodium 119 mEq/L, potassium 6.7 mEq/L, chloride 90 mEq/L, CO₂ 14 mEq/L.
- Urinalysis: leukocyte esterase and protein 3+, blood 2+, white blood cells 50 to 100/µL, moderate levels of bacteria.
- Urine culture positive for *Escherichia coli*.
- Aldosterone 875 ng/dL (normal for term infant <217 ng/dL).
- Ultrasound examination revealed presence of a utricle.

Management and Outcome

- Infant with pseudohypoaldosteronism secondary to urinary tract infection (Riepe, 2013).
- Infant treated with antibiotics and normal saline with resolution of hyponatremia and urinary tract infection.
- Urology follow-up to discuss urinary tract infection prophylaxis and need for removal of utricle.

The need for surgical intervention in DSD should be assessed on a case-by-case basis. The parents need to be informed about the risks and benefits of surgery. Surgery on the external genitalia should perhaps be reserved for individuals with significant discord between the sex of rearing and the appearance of the external genitalia.

The infant with a DSD and the family will have to cope with difficult psychosocial challenges throughout life. Physicians caring for these patients should ensure the integration of well-trained mental health professionals into the longitudinal care of these complex infants and children.

CONTROVERSY BOX

Gonadectomy in a 46,XY individual with ambiguous genitalia raised as a female is controversial. The risk of gonadal tumor is low if the testis is not dysgenetic. But the gonad can produce testosterone or DHT at puberty via alternative pathways or isoenzymes. For example, individuals raised as a female with 5α-reductase type 2 deficiency or 17β-HSD type 3 deficiency may virilize at puberty if the testes are left in place. Will the retention of testes in 46,XY DSD females promote male gender identity or cause irreversible virilization? Should a gonadectomy be done before a child can give assent/consent? Is it permissible to remove gonads so that a child raised as a female has perhaps a greater chance of having a female gender identity? Endocrinologists can suppress gonadal production of testosterone through the use of long-acting gonadotropin-releasing hormone analogues once the gonad becomes active in puberty. This may then permit the child or adolescent to make the decision as to whether or not to pursue gonadectomy at a later age.

Disorders of the Thyroid Gland

GRACE KIM, DEBIKA NANDI-MUNSHI, AND CAROLINA CECILIA DIBLASI

KEY POINTS

- An understanding of thyroid embryogenesis and the physiology of the thyroid gland in the perinatal period is important for proper interpretation of abnormal laboratory results and initiation of appropriate treatment.
- Appropriate thyroid hormone function is essential for normal neurodevelopment in infancy and childhood. Hypothyroidism in the first year of life can result in significant deleterious effects on growth and neurologic injury.
- Delay in treatment of congenital hypothyroidism (CH) is the most common preventable cause of mental retardation.
- Neonatal screening can provide early diagnosis and can prevent delays in treatment. Newborn screening methods differ and may possibly miss rare forms of congenital hypothyroidism.
- Eighty-five percent of cases of permanent CH are associated with abnormal development of the thyroid gland.
- In preterm newborns, thyroid hormone levels may fall because of immaturity of the thyroid gland, but these changes may be exacerbated by complications of prematurity.
- Thyroid metabolism can be affected by exogenous sources of iodine, dopamine infusions, blood transfusion, and glucocorticoid treatment.
- The clinical manifestations of Graves disease in the newborn include irritability, flushing, diarrhea, vomiting, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos.
- There is concern for neurologic damage in infants with hemangiomas when hypothyroidism is occult and untreated.

Thyroid hormone is essential for normal fetal brain development and for growth and regulation of energy metabolism throughout infancy and childhood. The interactions of the hypothalamus and pituitary gland with the thyroid are integral to the maintenance of normal thyroid function. An understanding of thyroid physiology and embryogenesis of the thyroid gland in the perinatal period is important for proper interpretation of abnormal laboratory results and initiation of appropriate treatment. Additionally, the interplay of the different thyroid hormones maintains the appropriate balance where needed.

Regulation of Thyroid Function

The hypothalamic–pituitary–thyroid (HPT) axis functions as a typical feedback loop (Fig. 98.1). Triiodothyronine (T_3) levels in the pituitary gland direct secretion of thyroid-stimulating hormone (TSH). Also, an inverse relationship exists between thyroid hormone

formation and iodide level in the thyroid. Subsequently, the rate of hormone production is not affected by rapidly changing levels of iodide, and the reservoir of thyroid hormone balances against quick changes in hormone synthesis.

TSH, produced in the anterior pituitary, is the chief player in thyroid gland function and morphology. TSH provides negative feedback by decreasing synthesis of thyrotropin-releasing hormone (TRH) from the hypothalamus, as well as blocking the action of TRH that stimulates TSH release (Melmed et al., 2016). Release of TSH fuels uptake of iodide by the thyroid gland and accelerates many steps in thyroid hormone synthesis. It also drives growth and vascularization of the thyroid gland itself. Both T_3 and thyroxine (T_4) provide negative feedback to TSH secretion, while TRH determines the setpoint. Given the logarithmic relationship between free T_4 (fT_4) and TSH, TSH levels are a sensitive indicator of thyroid hormone status.

Thyroid Hormone Synthesis

Synthesis of thyroid hormone is initiated by entry of iodide molecules into the follicular cell of the thyroid gland via the sodium–iodide transporter; these are then transported into the colloid. Once they are in the thyroid gland, oxidation of iodide occurs, after which it is quickly associated with thyroglobulin (TG). Organification of the iodide forms tyrosine residues, which are then coupled to form the two active thyroid hormones: T_4 and T_3 . This complexed TG, which resides in the colloid of the thyroid gland, serves as the reservoir for production of T_3 and T_4 . Thyroid hormones are then moved via endocytosis into the follicular cell. This vesicle fuses with lysosomes, after which T_4 and T_3 are dissociated from TG via hydrolysis and eventually released into the bloodstream. Residual monoiodothyronine (MIT) and diiodothyronine (DIT) are deiodinated and enter the synthesis cycle again along with iodide (I^-) and tyrosine. Important steps in thyroid hormone synthesis are summarized in Fig. 98.2.

Serum Protein Binding and Transport

In the circulation, T_3 and T_4 are transported by attachment to binding proteins that include T_4 -binding globulin (TBG), T_4 -binding prealbumin (TBPA), and albumin. These binding transport proteins are produced in the liver. Production of these proteins increases through the latter half of gestation and is stimulated by estrogen. Free thyroid hormone levels appear to remain constant despite the increase in total hormone concentrations because of an increase in binding protein production.

• **Fig. 98.1** The hypothalamic–pituitary–thyroid axis. Thyroid stimulating hormone (TSH) is secreted in response to TSH-releasing hormone (TRH) and stimulates secretion of thyroxine (T₄) and triiodothyronine (T₃) from the thyroid. T₃ and T₄ have actions in peripheral tissues and exert negative feedback on the hypothalamus and the pituitary.

The serum concentration of T₄ is vastly greater than that of T₃, by a factor of 50–100. The primary transport protein (~75% of T₃ and T₄) is TBG. The remaining 25% of thyroid hormone is equally distributed between TBPA and albumin. The fT₄ concentration more precisely reflects the metabolic status, in comparison with total T₄ or T₃. This is because only unbound hormone can enter cells to exert its action (Benvenega, 2013).

Embryogenesis of Hypothalamic–Pituitary–Thyroid Axis

The thyroid gland is the first endocrine organ to develop in the fetus. The development of the thyroid gland and the HPT axis occurs in two phases. The first phase is characterized by the embryogenesis of the structures involved, and the second phase is characterized by the maturation of the HPT axis, which will be described later (Polak and Luton, 2014). By about 3 weeks of gestation, the rudimentary beginnings of the hypothalamus have developed. Subsequently, anlagen from the floor of the forebrain and the Rathke pouch converge to form the pituitary gland. By 14 to 15 weeks of gestation, this embryologic structure has become the mature pituitary gland (Van Vliet and Deladoey, 2014). Detection of TSH has been observed as early as 10 to 12 weeks of gestation (Kratzsch and Pulzer, 2008).

A programmed sequence of transcription and homeobox factors (e.g., transcription termination factor 2 [TTF-2], forkhead box

E1 [FOXE-1], paired box 8 [PAX8]) directs thyroid embryogenesis. Thyroid gland development begins with convergence of three structures: the median anlage from the floor of the pharyngeal pouch (caudal end of the foregut) and two lateral anlagen from the fourth pharyngobranchial pouch. The median anlage is visible by day 22 after conception. The lateral anlagen develop into a pair of ultimobranchial bodies from which the calcitonin-producing parafollicular C cells arise. Between day 32 and day 48 after conception, this primordial thyroid structure breaks off from the pharyngeal pouch and completes its migration to the pretracheal region. Little is known about the molecular factors involved in this migration; however, FOXE-1 has been implicated in cases of thyroid ectopy (Szinnai, 2014).

By 4 weeks after this descent is complete, functional and structural changes are mature, and the thyroid is capable of producing thyroid hormone. Follicles fill with colloid. By 12 weeks of gestation, the thyroid gland is now able to take up iodide, synthesize TBG, and produce hydrogen peroxide (H₂O₂) at the apical membrane—all steps required for thyroid hormone production. T₄ has been detected in human fetal blood as early as 11 to 12 weeks of gestation (Calvo et al., 2002). This accrual of the ability to produce thyroid hormone coincides with maturation of the hypothalamus and pituitary gland with production of TRH and TSH.

Fetal–Placental–Maternal Thyroid Interaction

The placenta is of utmost importance in fetal thyroid physiology as it regulates the passage of maternal thyroid hormone to the fetus (Fig. 98.3). Thyroid hormone is paramount for normal neurodevelopment. Maternal-to-fetal transfer of T₄ is essential, especially in the first trimester, when the fetal thyroid axis has yet to mature.

Multiple clinical studies have shown the deleterious effects of inadequate maternal thyroid hormone levels (Haddow et al., 1999; Pop et al., 2003; Li et al., 2010). However, the placenta is not able to address maternal hypothyroidism, as fetal T₄ levels reflect maternal levels (Chan et al., 2009). With the landmark study by Vulsma et al. (1989), it was shown that T₄ does cross the placenta, contradicting previous concepts: placental transfer of T₄ in athyreotic fetuses resulted in levels that were 25%–50% of those of normal term newborns. Thus the hypothyroid fetus in a euthyroid mother has some protection; accordingly, a hypothyroid fetus in a hypothyroid mother has the most substantial deficits (Glinioer, 2001).

TSH does not cross the placenta; however, TRH does. During pregnancy, maternal thyroid axis changes result in increases in fT₄ levels early and maintenance of higher levels until birth (Fig. 98.4). This is a result of human chorionic gonadotropin produced by the placenta, which is homologous to TSH with some TSH-like activity (Moleti et al., 2014).

Although most of the transfer of the maternal thyroid hormone is dependent on maternal thyroid hormone concentrations, plasma membrane thyroid hormone transporters and metabolism via deiodinases (DIs) also play a role. Thyroid hormone transporters are found in the apical and basolateral membrane of the placenta. Several transporters have been discovered in the placenta (monocarboxylate transporters, L-type amino acid transporters, and organic anion–transporting polypeptides) (Fujiwara et al., 2001; Visser et al., 2008). The placenta also has abundant type 3 DI, which is involved in metabolism of thyroid hormone in this milieu. T₃ is

• **Fig. 98.2** Steps involved in the synthesis of thyroid hormones: (1) iodide transport; (2) oxidation of I^- to I_2 ; (3) organization of I_2 into monoiodothyronine (MIT) and diiodothyronine (DIT); (4) coupling reaction of MIT and DIT to form triiodothyronine (T_3) and thyroxine (T_4); (5) endocytosis of thyroglobulin (TG); (6) hydrolysis of T_4 and T_3 ; T_4 and T_3 enter circulation; (7) deiodination of residual MIT and DIT, recycling of I^- and tyrosine.

• **Fig. 98.3** The placental role in thyroid metabolism. The placenta produces estrogens and human chorionic gonadotropin (hCG), which increase maternal thyroxine (T_4)-binding globulin (TBG) levels and stimulate maternal thyroid hormone production, respectively. Both activities tend to increase maternal T_4 and triiodothyronine (T_3) concentrations and inhibit maternal thyroid stimulating hormone (TSH) secretion. Iodide and TSH-releasing hormone (TRH) readily cross the placenta. In addition, the placenta synthesizes TRH. The placenta is impermeable to TSH and only partially permeable to T_4 and T_3 . rT_3 , Reverse triiodothyronine.

thought not to cross the placenta; however, this is not clear (Mitchell et al., 1992).

Iodide is taken up by the thyroid gland for thyroid hormone synthesis. There is free passage of iodides between the mother and the fetus. Large-quantity ingestion of iodine will decrease synthesis of T_4 transiently. This is due to decreased uptake via the sodium-iodide symporter. Typically, there is escape from this phenomenon in about 48 hours. However, cases of goiter and hypothyroidism have been reported with excessive iodine intake (Overcash et al., 2016). An adequate amount of iodine is still recommended for pregnant women, around 150 μ g per day according to the American Thyroid Association (Becker et al., 2006).

Miscellaneous other compounds can cross the placenta, affecting fetal thyroid function. TSH receptor-blocking antibodies (TRBAs), also known as TSH Binding Inhibitory Immunoglobulins, have been implicated in cases of transient neonatal hypothyroidism (Evans et al., 2011). In mothers with a history of Graves disease, thyroid-stimulating immunoglobulin (TSI) can lead to thyrotoxicosis in the neonate (Levy-Shraga et al., 2014). Antithyroid medications ingested by the mother can result in fetal goiter with or without hypothyroidism (Rosenfeld et al., 2009).

Thyroid System Maturation

The fetal thyroid gland is able to synthesize and secrete thyroid hormone after 12 weeks of gestation. As the pregnancy continues, the levels of f T_4 and T_4 continue to rise in step with the gestational age of the fetus. T_3 levels, however, remain low until about 30 weeks of gestation, after which they increase slowly until birth. This delayed rise in T_3 levels is due to low rates of conversion of T_4 to T_3 by type 1 DI and high activity of type 3 DI metabolizing T_3 .

• **Fig. 98.4** Relative changes in maternal and fetal thyroid function during pregnancy. The effects of pregnancy on the mother include a marked and early increase in hepatic production of thyroxine (T_4)-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). The increase in serum TBG level, in turn, increases serum T_4 concentrations; hCG has thyroid stimulating hormone (TSH)-like activity and stimulates T_4 secretion. The transient hCG induces increase in serum T_4 and inhibits maternal secretion of TSH.

to diiodothyronine (DIT) (Van Vliet and Deladoey, 2014). With an increased amount of type 1 DI produced by the liver after 30 weeks, there is increased conversion of T_4 to T_3 in the liver and decreased metabolism of T_3 by placental type 3 DI, resulting in the steady rise until delivery. TSH has also been detected at 12 weeks of gestation, with subsequent increases in its level in parallel with increases in fT_4 level (LaFranchi, 1999a). The level of reverse T_3 (rT_3) is quite high early in the third trimester because of placental type 3 DI activity converting T_4 to rT_3 and T_3 to DIT (Fig. 98.5).

Fetal Thyroid Hormone Metabolism

The thyroid gland is the body's only source of T_4 . Conversion of T_4 to T_3 peripherally contributes most of the circulating T_3 . This conversion is accomplished by a group of three DIs, types 1, 2, and 3 (see Fig. 98.5). T_3 , with its greater affinity for the thyroid hormone receptor, is the active form of thyroid hormone. T_3 is

derived from deiodination of the outer ring of T_4 . Conversely, deiodination of T_4 at the inner ring produces the inactive rT_3 (Kuiper et al., 2005).

Type 2 and type 3 DIs are selective in their action, performing deiodination on only the outer ring and inner ring, respectively. Type 1 DI is nonselective, with deiodination at the outer ring converting T_4 to T_3 and deiodination at the inner ring producing rT_3 from T_4 . Type 1 DI is produced in the liver, kidney, and thyroid. Type 1 DI is inhibited by propylthiouracil and rT_3 and stimulated by thyroid hormone. Type 2 DI is primarily found in brain, pituitary, placenta, skeletal muscle, heart, thyroid, and brown adipose tissue and is not sensitive to propylthiouracil and is inhibited by thyroid hormone. It converts T_4 to T_3 . Type 3 DI is found primarily in fetal tissues, including the placenta, brain, and skin. Type 3 DI converts T_4 to rT_3 and T_3 to DIT (Huang, 2005).

During pregnancy, fetal DI levels vary with time and are reflective of thyroid hormone concentrations. Type 1 DI in hepatic tissues remains quiescent until late in gestation, resulting in a late rise of fetal T_3 levels. Type 3 DI activity is responsible for high rT_3 levels in the fetus. The interplay of these enzymes is critical to normal brain development. Given that both type 1 and type 2 DI are sensitive to thyroid hormone levels, a hypothyroid fetus will have increasing type 2 DI activity in the brain and decreasing type 1 hepatic activity, resulting in more T_4 in the brain, at which point it is converted to T_3 by type 2 DI (Fisher et al., 1994).

Extrauterine Thyroid Adaptation

At birth, fT_4 levels in the newborn are slightly below that of the maternal concentration, and the T_3 level is quite low in umbilical cord blood. Also, at this time, partly in response to cold and stress, there is a TSH surge that peaks at about 2–4 hours of life and then returns to its initial value within about 48 hours (Fig. 98.6). T_3 and T_4 levels also rise within a few hours of birth and reach their peak by the end of the 24 hours. TSH, as well as extrathyroidal conversion of T_3 to T_4 by type 1 and type 2 DIs, contributes to this surge of thyroid hormone (Salvatore et al., 2016). During the next 4 to 5 weeks of life, T_4 and T_3 levels progressively decrease to levels just above the normal range of children. By 1 month of age, TSH level has declined to about 5 mU/L (LaFranchi, 1979) and declines further to a near-adult range of 0.5–4 mU/L by the second month (Baloch et al., 2003).

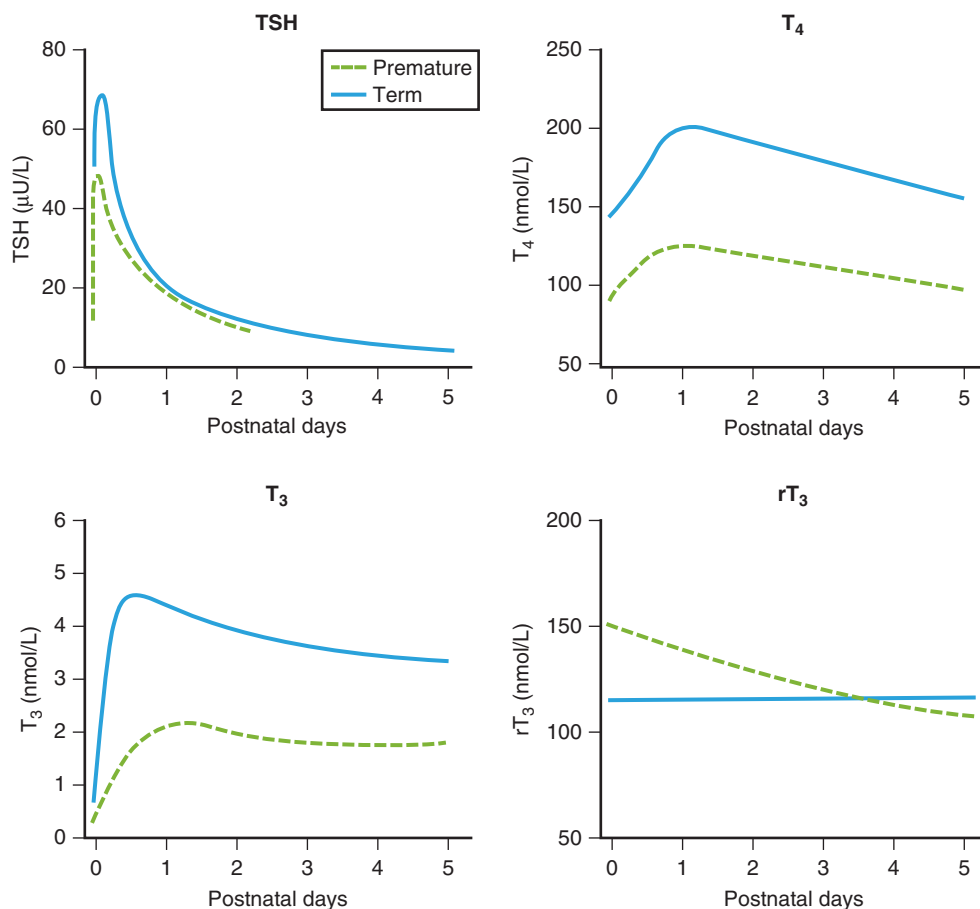

Infants born prematurely appear to have an attenuated TSH surge. This is due to an immature HPT axis. T_3 and T_4 levels also have a blunted rise in comparison with the levels in term newborns. TSH level can peak at about 40 mU/L by 30 minutes (LaFranchi, 1999b). Many factors need to be taken into account when one is assessing thyroid function in preterm infants. As many preterm newborns have other complications, such as respiratory distress syndrome or nutritional problems, serum T_4 , and especially T_3 , concentration may fall to low levels as a result of immaturity of the thyroid gland, as well as reduced TBG production. Illness additionally causes suppression of the hypothalamic-pituitary-thyroid axis, impairs conversion of T_4 to T_3 , and increases type 3 DI activity (Salvatore et al., 2016).

Congenital Hypothyroidism

Congenital hypothyroidism (CH) is a common cause of mental retardation if not treated promptly. The overall incidence is 1 in 2500 to 1 in 3000 newborns (Waller et al., 2000; Harris and Pass, 2007). Higher incidence rates have been reported in certain

• **Fig. 98.5** Enzymatic conversion of iodothyronines. $D1$, Type 1 deiodinase; $D2$, type 2 deiodinase; $D3$, type 3 deiodinase.

• **Fig. 98.6** Postnatal thyroid stimulating hormone (TSH), thyroxine (T_4), triiodothyronine (T_3), and reverse T_3 (rT_3) secretion in the term and premature infant in the first week of life. (Adapted from www.thyroidmanager.org, the free online thyroid textbook. In Brown R, Larsen PR, De Groot LJ, eds: *Thyroid gland development and disease in infants and children*, South Dartmouth, MA, 2009, Endocrine Education, Inc, Chapter 15, Figure 15-4, p 9.)

populations. The prevalence rates of CH can differ with sex, ethnicity, and birthweight. Twice as many female as male infants are affected. Compared with whites, the prevalence of CH is higher in Asians and Hispanics and lower in blacks. A study noted an increased risk of CH in macrosomic (>4500 g) and low birthweight (<2000 g) infants (Waller et al., 2000). There is increased risk in infants with Down syndrome.

In most cases the disorder is permanent and results from an abnormality in thyroid gland development (dysgenesis or agenesis) or a defect in thyroid hormonogenesis. Less commonly, the altered thyroid function is transient, attributable to transplacental passage of maternal medication, maternal blocking antibodies, or iodine deficiency or excess. In rare cases, CH may result from a pituitary or hypothalamic abnormality (Rose et al., 2006). Potential causes are listed in Table 98.1. Regardless of the duration of the thyroid dysfunction, immediate treatment with levothyroxine (LT₄) in the newborn period is needed to prevent cognitive or neurodevelopmental decline. The developing fetal brain is protected in utero by an adequate source of T₃, supplied by local deiodination of maternal T₄ in the fetal brain.

TABLE 98.1 Thyroid Disorders and Their Approximate Incidence in the Neonatal Period

| Disorder | Incidence |
|--|-----------------------------|
| Thyroid Dysgenesis | 1 in 2500 to 1 in 4000 |
| Agenesis | |
| Hypogenesis | |
| Ectopia | |
| Thyroid Dyshormonogenesis | 1 in 30,000 |
| TSH receptor defect | |
| Iodide-trapping defect | |
| Thyroid peroxidase defect | |
| H ₂ O ₂ generation defect | |
| Defect in thyroglobulin | |
| Pendred syndrome | |
| Dehalogenase defect | |
| TSH signaling defect: Albright hereditary osteodystrophy | |
| Transient Hypothyroidism | 1 in 12,000 to 1 in 30,000 |
| Drug induced | |
| Maternal antibody induced | |
| Idiopathic | |
| Hypothalamic–Pituitary Hypothyroidism | 1 in 80,000 to 1 in 100,000 |
| Hypothalamic–pituitary anomaly | |
| Panhypopituitarism | |
| Isolated TSH deficiency | |

H₂O₂, Hydrogen peroxide; TSH, thyroid stimulating hormone.

Clinical Manifestations

The diagnosis of hypothyroidism should be considered in any infant with prolonged jaundice, transient hypothermia, an enlarged (>1 cm) posterior fontanel, failure to feed properly, or respiratory distress with feeding (Pezzuti et al., 2009). Approximately one-third of maternal T₄ crosses to the fetus at term. With a half-life of 6 days, the maternal T₄ will be metabolized and excreted by 3 to 4 weeks of age (LaFranchi, 2011). The classic signs evolve during the first few weeks after birth. Fetal growth is normal; however, there is delay in bone maturation and a rapid reduction in growth rate after birth (Van Vliet, 2005), with progressively worsening myxedema in subcutaneous tissues and tongue. The thickened tongue becomes protuberant, and increasing difficulty in nursing and handling salivary secretions is noted. The cry is hoarse because of myxedema of the vocal cords. Additional signs and symptoms include marked muscular hypotonia; constipation; thick, dry, cold skin; long and abundant coarse hair; large tongue; abdominal distention; umbilical hernia; hyporeflexia; bradycardia; hypotension with narrow pulse pressure; anemia; and widely patent cranial sutures. Goiter can be present. The typical facies are characterized by a depressed nasal bridge, a relatively narrow forehead, and puffy eyelids (Foley, 1994). The cardiac silhouette may be enlarged, and the electrocardiogram shows low voltage and a prolonged conduction time. Some of the signs and symptoms are present by 6 to 12 weeks postnatally, especially lethargy, constipation, and umbilical hernia. The cretinoid facies and growth retardation become increasingly obvious during the first several months of life.

Nonspecific symptoms and signs associated with hypothyroidism are listed in Table 98.2. Because clinical manifestations of hypothyroidism may not appear until weeks after birth, even in athyreotic infants, newborn screening has enabled pediatricians to identify newborns with low thyroid hormone production and to initiate

TABLE 98.2 Clinical Signs and Symptoms of Congenital Hypothyroidism in Infancy

| Age/Manifestation | Frequency (%) |
|----------------------------------|---------------|
| 0–7 Days | |
| Prolonged jaundice >3 days | 73 |
| Birthweight >4 kg | 40 |
| Poor feeding | 40 |
| Transient hypothermia | 38 |
| Large posterior fontanel (>5 mm) | 32 |
| 1–4 Weeks | |
| Failure to gain weight | 45 |
| Constipation | 35 |
| Hypoactivity | 33 |
| 1–3 Months | |
| Failure to thrive | 90 |
| Umbilical hernia | 49 |
| Macroglossia | 43 |
| Myxedema | 40 |
| Hoarse cry | 30 |

therapy within the first 2 weeks of life, before the development of signs and symptoms (Rose et al., 2006).

Neonatal Screening for Hypothyroidism

Newborn screening programs for CH avoid delay in its diagnosis, because signs and symptoms of CH may not manifest themselves for several weeks. The screening programs are designed to detect elevated serum TSH levels in blood samples collected on filter paper. Some programs measure TSH directly, and others measure TSH in those samples with low or low-normal T_4 concentrations. Screening programs have been established in industrialized countries: in the United States, western Europe, parts of eastern Europe, Japan, Australia, and parts of Asia, South America, and Central America. However, many countries still do not have a nationwide program for neonatal thyroid screening.

Both methods of screening—primary TSH/backup T_4 method and primary T_4 /backup TSH method—appear to be capable of detecting almost all infants with primary CH. In addition, an increasing number of programs use a combined TSH plus T_4 approach.

Primary CH is associated with a low serum T_4 and fT_4 concentration and a high TSH concentration in umbilical cord blood or neonatal blood samples. It is estimated that 5%–8% of affected infants can escape detection by newborn screening because of a delayed elevation in serum TSH concentration or because of errors in sample collection or laboratory routine. In addition, infants with TSH deficiency who have normal TSH levels are not detected, because most newborn screening programs report only those infants with elevated TSH levels. Infants with central hypothyroidism may have normal or low TSH. Normal TSH would be inappropriate in the setting of low thyroid hormone levels. Newborn screens that use elevated TSH to detect congenital hypothyroidism will miss diagnosing these infants. Infants with signs or symptoms suggestive of thyroid dysfunction (Table 98.2) should be investigated regardless of previous screening results. Determination of serum fT_4 , T_4 , and TSH values is necessary in any infant with suspicious clinical or laboratory findings.

Every infant should be tested before discharge from the nursery, optimally by 2 to 4 days of age. The practice of early hospital discharge (before 48 hours of age) has led to an increased frequency of false-positive results because of the normal physiologic TSH surge that occurs after birth. Infants screened before 48 hours of age require the newborn screen to be rechecked by the primary care physician at 2 weeks of life. False-negative results may occur by the screening of a very sick newborn or after transfusion.

Accurate screening results depend on good-quality blood samples. Blood samples should be collected on approved forms of filter paper, dried at room temperature, and not subject to excessive heat. Capillary blood samples are placed in the circular areas to fill and saturate them, applied to one side only. Filter paper should not be handled or placed on wet surfaces (Rose et al., 2006).

Thyroid Function Tests

When the diagnosis of CH is suspected, thyroid function tests should be performed. It is advisable to assess fT_4 , T_4 , TSH, and TG levels. Measurements of T_3 , rT_3 , free T_3 , and T_3 resin uptake (T3U) are not indicated (Rose et al., 2006).

Elevated serum TSH value is the most sensitive and specific test to confirm the diagnosis of primary hypothyroidism. Typical laboratory findings for primary hypothyroidism include elevated

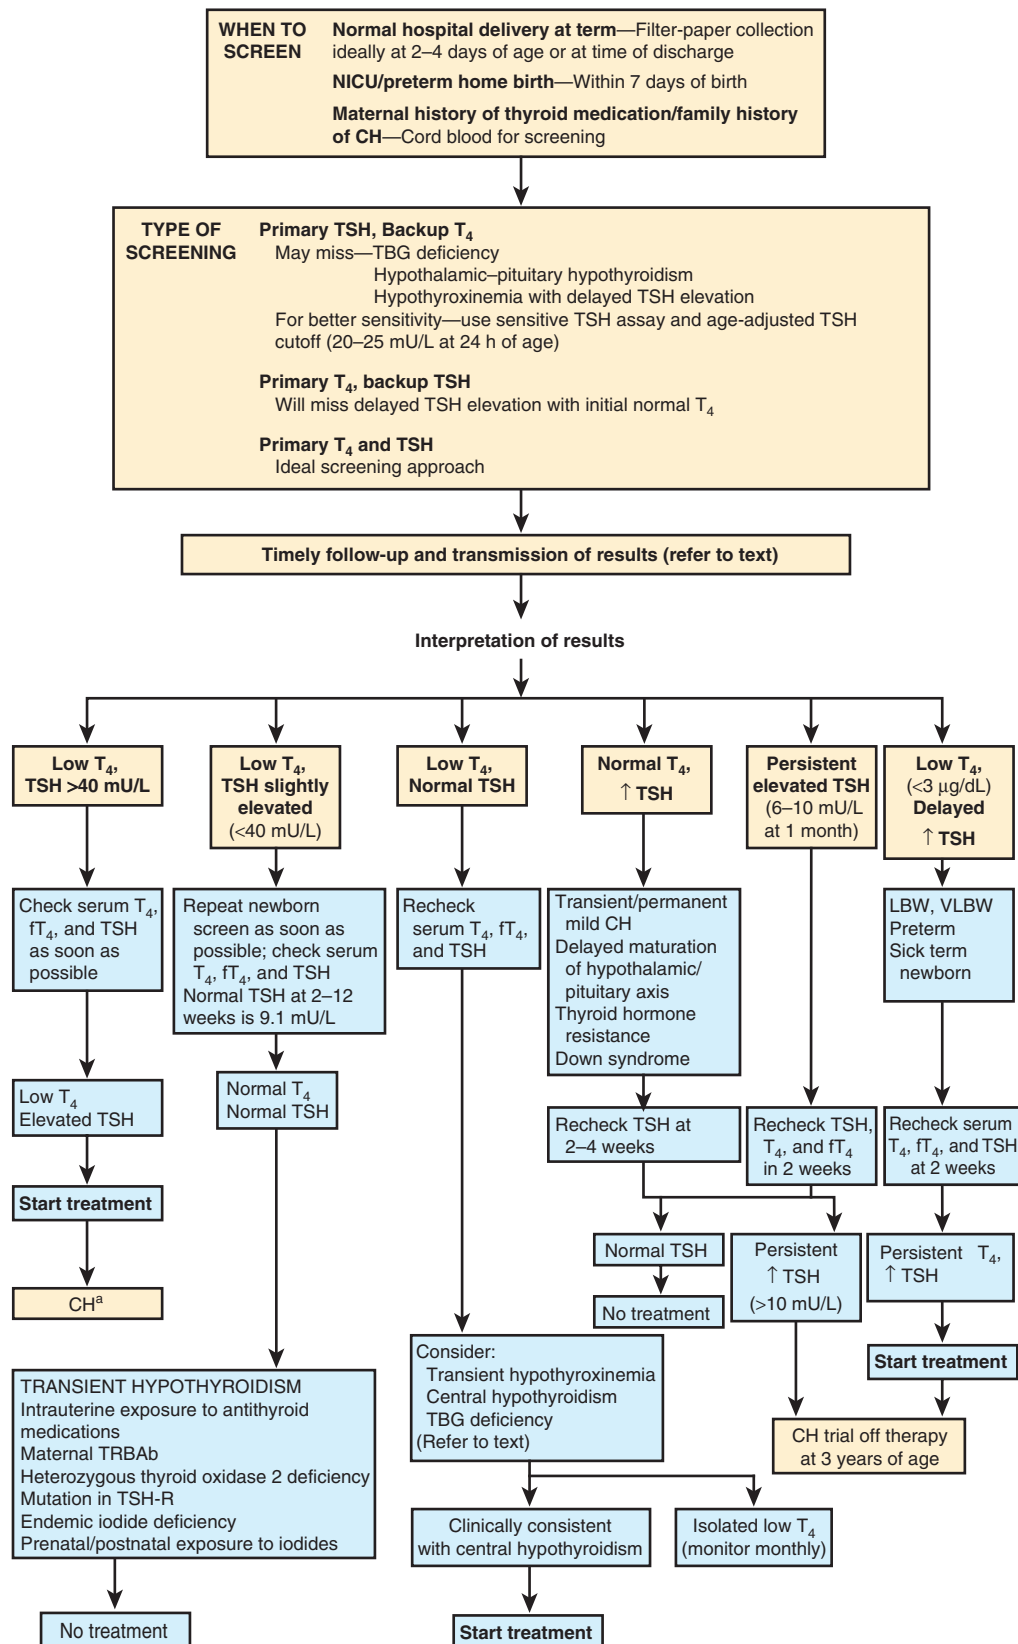

TSH levels, with T_4 and fT_4 values in the low or low-normal range. A low or undetectable TG concentration (Sobrero et al., 2007) with TSH level elevation confirms a dysgenetic or absent thyroid gland (Djemli et al., 2004), whereas a high TG concentration with TSH level elevation suggests an organification defect (Vulsma et al., 1991). In central hypothyroidism, TSH level is usually normal, T_4 level is low normal, and fT_4 level is in the lowest third of normal (Van Tijn et al., 2008).

Interpreting Thyroid Function Tests

When interpreting thyroid function tests, it is critically important to take into account the day of life on which the samples were drawn. The recommended period for newborn screening of thyroid function is at 24 hours of life. If screening is done at less than 24 hours of life, it must be redone, regardless of the results. After 24 hours of life, a TSH value greater than 40 μ U/L is highly suggestive of hypothyroidism, but confirmatory testing is required. A TSH value above the normal limit for the hours of life and gestational age but below 40 mU/L is indeterminate. Therefore repeated testing is necessary, and the primary care physician is informed of the need to obtain a second screen (Fig. 98.7). The practice of early hospital discharge (<48 hours of age) has led to a higher rate of indeterminate results.

Eight percent to 10% of infants with CH have TSH values between 20 and 40 mU/L. One in 12 to 1 in 24 hypothyroid infants (1 in 50,000 to 1 in 100,000 newborns) will have a screening TSH level of less than 20 mU/L, with a delayed postnatal increase to hypothyroid levels (Hyman et al., 2007). Therefore any infant with suspicious screening or sampling results requires confirmatory testing with measurement of serum fT_4 , T_4 , and TSH concentrations (Rose et al., 2006).

The biochemical profile of hypothalamic–pituitary hypothyroidism comprises low serum T_4 concentration with a normal TSH value (1 in 80,000 to 1 in 100,000). A similar biochemical profile characterizes TBG deficiency (1 in 5000). However, the two states can be differentiated by further assessment of TBG and fT_4 levels. A low serum TBG concentration and a normal fT_4 level identify patients with TBG deficiency. In contrast, a low or low-normal fT_4 level and a normal TBG level identify a patient with hypothalamic–pituitary hypothyroidism. An infant with a low fT_4 concentration needs to be carefully examined for evidence of hypothyroidism, and other tests of pituitary function should be conducted. TRH stimulation testing can be used to differentiate between primary and central hypothyroidism. TRH, however, is not available in the United States. A subnormal TSH response to TRH or a normal but delayed and prolonged TSH response to TRH is indicative of central hypothyroidism (Van Tijn et al., 2008). TSH deficiency may be isolated or associated with other pituitary hormone deficiencies. Frequently it is not possible to discriminate between secondary and tertiary hypothyroidism, so the most useful diagnostic term is *central hypothyroidism*. The presence of midline facial abnormalities, hypoglycemia (growth hormone and/or adrenocorticotrophic hormone deficiencies), microphallus (gonadotropin and growth hormone deficiencies), nystagmus or blindness, or polyuria (antidiuretic hormone deficiency) should suggest the possibility of a hypothalamic abnormality. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can manifest itself as CH. Mutations in *HESX1* have been described in septo-optic dysplasia. Alternatively, multiple pituitary hormone deficiencies suggest a genetic defect in the cascade leading to fetal pituitary formation, such as in *PROP1*, *LHX3*, *LHX4*, and *POU1F1*.

• **Fig. 98.7** Algorithm for evaluating congenital hypothyroidism (CH) on the basis of newborn screening results. fT_4 , free thyroxine; LBW, low birthweight; NICU, neonatal intensive care unit; T_4 , thyroxine; TBG, thyroxine-binding globulin; TRBAbs, thyroid stimulating hormone receptor–blocking antibody; TSH, thyroid-stimulating hormone; TSH-R, thyroid stimulating hormone receptor; VLBW, very low birthweight. (Modified from Rose SR, Brown RS, Foley T, et al. Update of newborn screening and therapy for congenital hypothyroidism. *Pediatrics*. 2006;117:2290–2303.)

Isolated TRH deficiency may cause low-normal T_4 and low-normal TSH levels. Mutations have been identified in the TRH gene, TRH receptor gene, and the gene encoding the β subunit of TSH.

Newborns who are born before term, of low birthweight (<2500 g) or very low birthweight (<1500 g), and ill are found among those with this set of laboratory values. In neonates/infants, inhibition of TSH causing low T_4 concentration can result from dopamine infusions or high-dose glucocorticoids (Rose et al., 2006).

A strategy of second screening should be considered for the following conditions: preterm neonates; low birthweight or very low birthweight neonates; ill newborns admitted to the neonatal intensive care unit; specimen collection within the first 24 hours of life; and multiple births.

Thyroid Dysgenesis

Eighty-five percent of cases of permanent CH are associated with abnormal development of the thyroid gland, which includes agenesis, ectopy, or hypoplasia of the gland. Thyroid ectopy accounts for approximately two-thirds of cases worldwide (LaFranchi, 1999a). There is female predominance associated with ectopic glands. Ectopic locations of the thyroid gland include lingual, neck, and substernal locations. Most cases are sporadic; however, more recent studies show evidence of genetic factors being involved in the pathogenesis.

A unique combination of transcription factors control the embryonal development of the thyroid gland. Mutations in the genes encoding these transcription factors can lead to varying degrees of abnormalities, from athyreosis to normal glands. Other clinical features can be associated as noted in Table 98.3. Thyroid ectopy, the most common form of thyroid dysgenesis, remains unexplained.

TABLE 98.3 Genes and Thyroid Development

| Gene | Thyroid Phenotype | Other Features |
|---------------------|----------------------------|---|
| <i>TTF-2/FOXE-1</i> | Athyreosis | Cleft palate, choanal atresia, kinky hair, bifid epiglottis |
| <i>TTF-1/NKX2.1</i> | Athyreosis to normal gland | Respiratory distress syndrome, developmental delays/hypotonia, ataxia/choreoathetosis |
| <i>PAX-8</i> | Athyreosis to normal gland | Cysts within thyroid remnants, kidney and urinary tract malformations |
| <i>GLIS3</i> | Athyreosis to normal gland | Congenital glaucoma, deafness, liver/kidney and pancreatic abnormalities |
| <i>TSHR</i> | Athyreosis to normal gland | None |
| <i>NKX2.5</i> | Athyreosis, ectopy | Cardiac defects |

FOXE-1, Forkhead box E1; *GLIS3*, GLIS family zinc finger 3; *PAX-8*, paired box 8; *TSHR*, thyroid stimulating hormone receptor; *TTF-1*, transcription termination factor 1; *TTF-2*, transcription termination factor 2.

Mutation in *NKX2-5*, which encodes a transcription factor involved in heart morphogenesis, has also been reported to be associated with thyroid dysgenesis (Dentice et al., 2006).

Extrathyroidal abnormalities occur at a higher frequency in children with CH. The most frequent malformations associated with thyroid dysgenesis are cardiac, largely septation defects (Devos et al., 1999). Other relatively common malformations include anomalies of the gastrointestinal tract, nervous system, and eyes (Olivieri et al., 2002; Kreisner et al., 2005; Gu et al., 2009).

The biochemical picture can differ depending on the amount of thyroid tissue remaining. The presence of residual thyroid tissue is evident by detectable TG levels and normal or near-normal T_3 levels with low T_4 and elevated TSH values. The presence of residual thyroid tissue can be confirmed with a thyroid scan.

Thyroid Dyshormonogenesis

The remaining 10%–15% of cases of CH involve defects in synthesis of thyroid hormone. Hereditary defects in virtually all of the steps of thyroid hormone synthesis, secretion, and action have been described (Fig. 98.8). These patients often have a normally located and normal-sized gland. Thyroid enlargement can present at birth or even before, but more commonly goiter develops later in life. The inheritance pattern is autosomal recessive (Topaloglu, 2006).

Defects associated with trapping of iodide or in the oxidation or organification of iodide can result in dyshormonogenesis. These mutations include:

1. Sodium–iodine symporter defect. The gene encoding the sodium–iodine symporter is *SLC5A5* on chromosome 19. Hypothyroidism presents most frequently in the neonatal or infantile period. Patients have goiter on physical examination or ultrasound imaging, contrasting with limited or absent uptake on scintigraphy.
2. Thyroid peroxidase (TPO) defect. TPO is the enzyme responsible for iodide oxidation, organification, and iodothyrosine coupling. Mutations in the thyroid peroxidase gene are the most common cause of thyroid dyshormonogenesis. The enzyme is located at the apical membrane of the follicular cell. The clinical presentation is permanent goitrous, CH, high uptake on thyroid scintigraphy, and a high serum TG level.
3. Defects in H_2O_2 generation. Dual oxidase 1 and dual oxidase 2 are enzymes that generate H_2O_2 at the apical membrane.
4. TG defect. TG is an iodinated glycoprotein. The TG gene is located on chromosome 8. TG serves as the matrix for the synthesis of T_4 and T_3 and the storage of thyroid hormone and iodine. It is the essential substrate for organification and the major protein component of the colloid in the follicular lumen. Goiter and hypothyroidism manifest themselves at birth or before, and patients have low or undetectable TG levels.
5. Pendred syndrome is an autosomal recessive disorder associated with a partial defect in iodine organification, goiter, and sensorineural deafness. It is caused by mutations in the *SLC26A4* gene, on chromosome 7, which encodes the chloride–iodide transporter pendrin. The gene is expressed in the cochlea, thyroid, and kidney. Pendrin functions to maintain the endocochlear potential and is involved in the apical efflux of iodide in the thyroid follicular cells (Kopp et al., 2008). The thyroid phenotype is usually mild and is seldom identified by neonatal TSH screening. Goiter development and hypothyroidism are variable and depend on nutritional iodine intake.
6. Dehalogenase defects. MIT and DIT, the main iodinated by-products of thyroid hormonogenesis, are deiodinated in the

• **Fig. 98.8** A thyroid follicular cell, indicating areas of possible defects in thyroid hormone synthesis (e.g., thyroid dysmorphogenesis). *ADP*, Adenosine diphosphate; *AMP*, adenosine monophosphate; *cAMP*, cyclic AMP; *ATPase*, adenosine triphosphatase; *DIT*, diiodothyronine; *DuOX2*, dual oxidase 2; *K⁺*, potassium ion; *MIT*, moniodothyronine; *Na⁺*, sodium ion; *NIS*, sodium-iodide symporter; *P_i*, inorganic phosphate; *T₃*, triiodothyronine; *T₄*, thyroxine; *Tg*, thyroglobulin; *TPO*, thyroid peroxidase; *TSH*, thyroid stimulating hormone; *TSHR*, thyroid stimulating hormone receptor. (Modified from Van Vliet G, Deladoey J. Disorders of the thyroid in the newborn and infant. In: Sperling MA, ed. *Pediatric Endocrinology*. 4th ed. Philadelphia, PA: Saunders; 186–208.)

thyroid cell by dehalogenase. In this way iodine is conserved within the thyroid gland for another cycle of synthesis of thyroid hormone (Topaloglu, 2006). Patients with iodothyronine dehalogenation defects have goiter and CH. The diagnostic hallmark is the presence of MIT and DIT in large amounts in the urine.

Central Hypothyroidism

Congenital central hypothyroidism is uncommon, and isolated TRH/TRH receptor/TSH β subunit deficiency is exceedingly rare. In the United States the combined incidence of secondary and tertiary hypothyroidism is about 1 in 80,000 to 1 in 100,000 births. Studies in the Netherlands suggest a higher incidence of 1 in 21,000 (Van Tijn et al., 2005; Kempers et al., 2006). Congenital central hypothyroidism is often associated with mutations in the gene that encodes transcription factors involved with pituitary development, including *Pit-1*, *LHX3*, *LHX4*, *POU1F1*, and *HESX1*, and can be associated with other hormone deficiencies.

Other midline facial, cranial, or intracranial defects should suggest the possibility of hypopituitarism, including altered functioning of the HPT axis. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can be manifested as secondary or (more commonly) tertiary hypothyroidism. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and adrenocorticotrophic hormone deficiencies), polyuria (from antidiuretic hormone deficiency), or a small phallus in boys or undescended testicles (from gonadotropin deficiency), whether or not accompanied by the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect septo-optic dysplasia. Prolonged jaundice, with unconjugated hyperbilirubinemia in CH and conjugated hyperbilirubinemia in adrenocorticotrophic hormone or cortisol deficiency can also be seen.

The consequences of central hypothyroidism are as neurologically devastating as those of primary hypothyroidism and therefore also require prompt treatment (Van Tijn et al., 2005). However, many newborn screening programs that use elevated TSH values to recognize thyroid dysfunction are inadequate in identifying newborns with central hypothyroidism.

Central hypothyroidism may be acquired during difficult delivery from traumatic brain injury; however, the fT₄ level may not become abnormal until 2 weeks of age.

The biochemical picture comprises normal or low TSH levels with low or low-normal T₄ levels and low fT₄ levels. Other laboratory evidence includes an abnormal TSH surge of less than 50% and a subnormal TSH response to a TRH stimulation test. Attention to other clinical features such as hypoglycemia, microphallus, and midline facial defects can lead to earlier identification of central hypothyroidism.

Down Syndrome and the Thyroid

The association of thyroid abnormalities in individuals with Down syndrome has been well known for several decades, with early case reports of hypothyroidism in individuals with trisomy 21 dating back to the 1960s (Daniels and Simon, 1968; Aarskog, 1969). Examination of fetal thyroid glands showed small thyroid follicles and that TSH concentration was consistently in the highest percentiles. This may suggest that the cause of thyroid problems in Down syndrome may be thyroidal in nature (Luton et al., 2012). Thyroid disorders seen in neonates and infants include overt CH (elevated TSH level with low T₄ level occurring at birth often detected by neonatal screening), subclinical hypothyroidism (elevated TSH level with normal T₄ levels), which can be congenital or acquired, acquired primary hypothyroidism (autoimmune or nonautoimmune), and rarely hyperthyroidism. Compared with the general population, CH is seen

more commonly in Down syndrome, with prevalence estimates ranging from 1.5% to 6.1% (King et al., 2014). Hypoplasia of the thyroid gland appears to be the commonest occurrence, whereas thyroid agenesis, dysgenesis, and ectopic thyroid are rare causes of CH (Kariyawasam et al., 2015). When the diagnosis of CH is clear with hyperthyrotropinemia and low T_4 level, treatment should be initiated and guidelines followed as for neonates without Down syndrome. What is more difficult to determine is the natural history and benefit of treatment in those with subclinical hypothyroidism. In one study, Claret et al. (2013) found that subclinical hypothyroidism resolved in 73.6% of young children with Down syndrome. The rate of remission was more significant in those without positive thyroid autoantibodies and without an enlarged thyroid gland. Evidence to support treatment of subclinical hypothyroidism includes improved growth (Sharav et al., 1988; Karlsson et al., 1998) and better cognitive and developmental outcomes (Van Trotsenburg et al., 2005). Also, there is little in the way of adverse effects of LT_4 treatment when thyroid function is being normalized. However, proponents of not treating subclinical hypothyroidism cite studies such as that of Claret et al. in which a large majority of those with subclinical hypothyroidism progress back to normal thyroid function. Hyperthyroidism is exceedingly rare in the newborn period, with onset most common in the adolescent years. Prevalence estimates for hyperthyroidism in the Down syndrome population range from 0% to 3% (King et al., 2014).

Consumptive Hypothyroidism

In infants with hepatic hemangiomas and in adults with hemangioendothelioma and malignant fibrous tumors, consumptive hypothyroidism may occur (Huang et al., 2000; Guven et al., 2005; Ruppe et al., 2005). During infancy, hemangiomas occur at a high frequency. Rapid growth during the first year of life can be observed, followed by involution and gradual regression by adolescence. The first year of life is a critical time for development (Huang et al., 2000). There is concern for neurologic damage in infants with hemangiomas when hypothyroidism is occult and untreated (Huang et al., 2000).

Hypothyroidism in hemangiomas involves increased expression of type 3 DI, and this action accelerates the rate of inactivation of thyroid hormone (Huang et al., 2000; Bessho et al., 2010). Type 3 DI catalyzes the conversion of T_4 to rT_3 and T_3 to DIT. rT_3 and DIT are inactive metabolites. Type 3 DI is particularly expressed in placenta, uterine endometrium, and neurons of the central nervous system (Larsen et al., 2008). Because of the high rate of thyroid hormone degradation, the hypothyroidism can be refractory to thyroid hormone treatment (Huang et al., 2000). These patients required very high doses of LT_4 and liothyronine to reduce serum TSH concentrations to normal (Huang et al., 2000). The presenting thyroid function tests showed low T_3 and T_4 levels and elevated TSH and serum rT_3 levels. With regression of the hemangioma, the thyroid hormone levels normalize (Huang et al., 2000).

Transient Primary Hypothyroidism

Transient CH is associated with excess maternal iodine ingestion or deficiency, maternal ingestion of antithyroid drugs, maternal TRBAs, heterozygous mutations of *DUOX2*, and large congenital hepatic hemangiomas (increased type 3 DI activity) (LaFranchi, 2011).

Hypothyroidism in the newborn period can be transient in 10% of cases (Rose et al., 2006). Studies in the Netherlands reported an incidence of 1 in 12,000 (Kempers et al., 2006). The newborn screen is initially abnormal, with a low T_4 level and a slightly elevated TSH level. However, repeated laboratory evaluation may demonstrate normalization of thyroid function test results, indicating a transient state of thyroid dysfunction. Because normalization may not occur for several months, thyroid hormone therapy should be initiated for protection of the infant's brain development if the TSH level remains elevated at 2 weeks of life. Therapy should be continued until age 3 years, when the child should be reevaluated. Transient hypothyroidism is more common in preterm infants.

Transplacental passage of maternal TRBAs (also known as *TSH-binding inhibitory immunoglobulins*) is estimated to cause transient thyroid dysfunction in 2% of newborns with CH (Brown et al., 1996). This transient thyroid dysfunction is often difficult to differentiate from permanent forms of hypothyroidism in the newborn period. These babies should be treated but will not require lifelong treatment.

Although many women with autoimmune disease are receiving thyroid replacement therapy, some may be clinically euthyroid and not receiving medications. Some of these women actually have hyperthyroidism or a history of Graves disease. Therefore diagnosis of thyroid dysfunction may be delayed until the postpartum period (Brown et al., 1996).

Maternal autoimmune thyroid disease may be associated with the production of TRBAs, which are a type of immunoglobulin G. TRBAs, like other immunoglobulins G, do not cross the placenta until after 16 weeks of gestation. TRBAs can cross the placenta and block TSH receptor in neonatal thyroid. Therefore the TRBAs do not affect thyroid embryogenesis, and infants do not develop permanent abnormalities in thyroid function (McKenzie and Zakarija, 1992). The severity and duration of the hypothyroid state in these newborns correlate with the initial titer of the blocking antibody and the duration of its presence in the infant's blood (Brown et al., 1996). Subsequent offspring remain at risk, because the antibodies can persist for up to 7 years in maternal sera (Brown et al., 1996).

The biochemical profile is that of CH, comprising low T_4 levels with elevated TSH levels that subsequently normalize. A thyroid scan is not helpful because the TRBAs are sufficiently potent to block TSH-induced uptake, which can be misleading and suggestive of thyroid agenesis. The distinguishing feature is the presence of TRBAs in newborn and maternal sera. However, routine screening for TRBAs is not currently indicated. This diagnosis should be suspected in any infant with CH born to a woman who has a history of autoimmune disease or if her previous offspring had thyroid disease (Brown et al., 1996).

Euthyroid Sick Syndrome

In acutely ill patients, thyroid function changes occur. It is hypothesized that alterations in thyroid hormone occur as an adaptive response to decreased basal metabolic rates in severely ill patients. The syndrome has been observed in sick infants and children (Carrascosa et al., 2008). These patients may have acute or chronic nonthyroidal illnesses. There is a decrease in T_3 activation in the periphery. The consistent finding is an abnormally low serum T_3 level, an increase in the rT_3 level, and reduction in TSH secretion. Normal TSH secretion can also be observed during mild or moderate illnesses. However, the TSH level is inappropriately low in the context of low serum T_3 levels (Larsen et al., 2008). T_4

level may be low or normal and fT_4 level may be normal, depending on the metabolic clearance rate of T_4 .

In preterm infants, T_4 , fT_4 , and T_3 levels are naturally lower than those in term infants, and rT_3 level is high (Fisher, 2007). Therefore thyroid tests in preterm infants may be hard to interpret especially when infants are sick from nonthyroidal diseases. The neonates most commonly with euthyroid sick syndrome are preterm infants with respiratory distress syndrome (Fisher, 2007; Tanaka et al., 2007). In the pediatric population, nonthyroidal illnesses associated with this syndrome include severe gastroenteritis, acute leukemia, anorexia nervosa, renal disease, burns, and surgical stress.

Euthyroid sick syndrome is found in patients with metabolic stress (e.g., diabetic ketoacidosis) and in pediatric patients who undergo cardiac surgery. There is a sharp rise in rT_3 level and a less dramatic fall in T_3 level by 2 hours after cardiac surgery. The rT_3 level returns to normal before the T_3 level. The changes in thyroid function test results are a continuum (Larsen et al., 2008). There is an inverse relationship between the severity of illness and the T_3 level. In euthyroid sick syndrome, abnormal thyroid function gradually reverts to normal function as the patient's primary illness resolves (Foley, 1994). During recovery, TSH level may be transiently elevated (up to 15 mU/L). Treatment with thyroid hormone is not indicated in these patients.

Transient Hypothyroxinemia of Prematurity

In preterm infants, postnatal thyroid hormone concentrations may differ from those in term infants. The thyroid hormone concentrations vary depending on the degree of prematurity. There are multiple causes, such as loss of maternal transfer of T_4 (Morreale de Escobar and Ares, 1998), immaturity of the HPT axis (Murphy et al., 2004), peripheral metabolism of iodothyronines (Pavelka et al., 1997), iodine deficiency (Ares et al., 1997), nonthyroidal illness (Fisher, 2007), and decreased TBG concentrations secondary to undernutrition or hepatic dysfunction (Klein et al., 1997). Thyroid metabolism can be affected by other factors: exogenous sources of iodine, dopamine infusions, blood transfusion, and glucocorticoid treatment.

In preterm infants, HPT immaturity is characterized by a limited neonatal TSH surge, decline in T_4 level in the first week of life, limited TSH response to hypothroxinemia, and a prolonged TSH response to TRH. Impairment of conversion of T_4 to T_3 and increases in type 3 DI activity may also influence thyroid function test results (LaFranchi, 1999b). Only in the third trimester does the hypothalamic TRH level begin to increase markedly (Fisher and Polk, 1989; LaFranchi, 1999b).

In transient hypothyroxinemia in premature infants (before 30 to 32 weeks of gestation), thyroid function tests show low T_4 and fT_4 levels with normal or low TSH levels. Thyroid hormone replacement has not been consistently effective in improving neurologic outcomes or reducing morbidity (Osborn, 2001; Valerio et al., 2004). Research efforts continue to investigate this question. At the current time, therapy is recommended only when a low T_4 level is accompanied by TSH level elevation (Osborn, 2001; Fisher, 2007).

Abnormalities in thyroid levels in preterm infants can be difficult to interpret when the infants are ill from nonthyroidal diseases. Preterm infants at risk should be monitored by serial determinations of fT_4 and TSH. LT4 treatment should be initiated if the illness state is expected to be persistent and TSH level remains elevated for 1 month or longer. A dose of 4–5 μ g of orally administered LT4 per kilogram was suggested in earlier dose studies (Amino and Hidaka, 2006).

Low Triiodothyronine Syndrome in Premature Infants

Changes in thyroid function test results during neonatal adaptation are qualitatively similar to those in term infants but occur at lower concentrations in premature infants. The neonatal surge and T_4 and T_3 peak responses diminish with decreasing gestational age (LaFranchi, 1999b). Premature infants have an increased susceptibility to neonatal morbidity, including birth trauma, acidosis, hypoxia, hypoglycemia, hypocalcemia, and infection, all superimposed on feeding disorders and relative malnutrition. All of these factors tend to inhibit peripheral T_4 to T_3 conversion. This action leads to the characteristic low T_3 state seen in premature infants. Serum T_3 values may remain low in these infants for 1 to 2 months. Other features of low T_3 syndrome in premature infants are variable but usually include elevated serum rT_3 levels and normal or low total serum T_4 concentrations. The fT_4 levels are usually in the range of those of healthy premature infants or of infants of matched gestational age and weight (LaFranchi, 1999b). TSH values are low in these infants. Treatment with thyroid hormone is not warranted (Osborn, 2001; Valerio et al., 2004).

Iodine Deficiency

Severe iodine deficiency is associated with cretinism. Iodine deficiency is a rare cause of transient hypothyroidism in North America but may occur in women who are dieting and thus not eating bread or using salt. Many countries have initiated salt iodination.

Iodine is a critical component of thyroid hormone synthesis; therefore even mild to moderate forms of iodine deficiency can result in an adverse outcome for the fetus. Although the mother with iodine deficiency may be clinically euthyroid with normal T_3 levels, maternal T_4 concentration is low in iodine deficiency. An increase in type 2 DI activity is detected in the fetus in response to iodine deficiency. Because normal development of the fetal neocortex is dependent on maternal T_4 , which is the primary source of cerebral T_3 , low levels of maternal T_4 place the infants at risk of neurologic cretinism. The fetus can experience several neurologic manifestations, such as deafness, motor deficits (spasticity, trunk rigidity, flexion dystonia, and muscle wasting), and mental retardation. Therefore it is imperative for the pregnant mother to receive an adequate supply of iodine early in pregnancy to avoid brain damage in the fetus (Bernal, 1999; Abalovich et al., 2007). Vitamin supplements that contain at least 250 μ g iodine should be used daily (Abalovich et al., 2007).

Preterm infants are at increased risk of iodine deficiency. The premature separation from the maternal supply of iodine and thyroid hormone prevents the preterm infant from accumulating adequate amounts of intrathyroidal hormone. Therefore the infant is unable to keep up with postnatal thyroid hormone demands. The biochemical profile of iodine deficiency in the newborn comprises low T_4 and elevated TSH levels. Iodine deficiency can lead to a transient state of thyroid dysfunction. An infant is sensitive to maternal iodine nutrition during fetal development.

The thyroid is also protected against iodide excess that might otherwise lead to hyperthyroidism. The sources of excess iodide are pharmaceutical: amiodarone, povidone–iodine, and radiographic dyes. The quantity of iodine organified to TG displays a biphasic response to increasing doses of iodide, at first increasing and then decreasing. The decreasing yield is termed the *Wolff–Chaikoff effect*.

The inhibition of iodothyronine formation is reduced over time, the escape phenomenon. This does not occur in the third-trimester fetus, so long-term high iodine intake must be avoided because it will cause fetal hypothyroidism.

Disorders of Thyroid Hormone Carrier Protein

Thyroid hormone in the circulation travels bound to transport proteins (TBG, TBPA, and albumin). As discussed previously, these carrier proteins are produced by the liver. The gene for TBG, the primary transport protein, is located on the long arm of the X chromosome; thus TBG defects are inherited in an X-linked manner. Given that TBG is the major transport protein, TBG deficiency causes significant thyroid changes in total thyroid hormone concentration. But given that free concentrations remain normal, these individuals are euthyroid. Treatment is not required. Primary T_4 newborn screening methods may be misleading, and confirmation with fT_4 levels is necessary before initiation of treatment.

Thyroxine-Binding Globulin Deficiency

The prevalence of TBG deficiency ranges from 1 in 2500 to 1 in 12,000 newborns (Mandel et al., 1993; Bhatkar et al., 2004; Larsen et al., 2008). The frequency in males is much higher, 1 in 2400 to 1 in 2800 males because it is an X-linked trait (Mandel et al., 1993; Abalovich et al., 2007). The transmission of this trait is usually from affected males to female offspring (Larsen et al., 2008). TBG deficiency has no clinical importance but leads to abnormal laboratory test results. Serum TBG levels are very low in affected males and are approximately half of normal in carrier females. In about half of the families with this trait, the TBG level shown by radioimmunoassay is very low. In the other half, the defect is partial; serum T_4 levels vary similarly. Affected individuals are euthyroid, with normal serum TSH responses to exogenous TRH. Treatment is not indicated (Bhatkar et al., 2004).

As many as 26 different mutations have been reported in the TBG gene. These mutations have included a single amino acid substitution or deletion leading to abnormal posttranslational processing (Larsen et al., 2008). Two novel mutations in the TBG gene identified most recently include a thymine (T) insertion at the beginning of intron 1 between nucleotides 2 and 3 and a T deletion in exon 1 leading to a truncated protein. Both mutations fail to produce a functional TBG molecule (Mannavola et al., 2006). In partial TBG deficiency, the defects are associated with altered TBG binding of T_4 (Larsen et al., 2008).

Females tend to have partial TBG deficiency whereas males generally have complete TBG deficiency. A partial deficiency comprises reduced TBG levels and normal TSH and fT_4 levels, with T_4 values at the lower limit of normal. A complete deficiency comprises undetectable TBG levels with normal TSH levels, normal fT_4 levels, and low levels of T_4 . Another useful laboratory tool is T_3RU , which is elevated in TBG deficiency (Noguchi et al., 1993). However, this is an indirect measure of TBG levels.

Thyroxine-Binding Globulin Excess

The prevalence of TBG excess is estimated to be 1 in 15,000 to 1 in 25,000 individuals. TBG excess is inherited as an X-linked

trait (Bhatkar et al., 2004). Individuals with increased levels of TBG have increased total serum T_4 concentrations, with normal TSH and fT_4 levels. Serum T_3 level is modestly increased. These individuals are euthyroid. In these individuals, TBG production rates and serum levels are correlated, suggesting that the mechanism for high TBG levels is increased production, presumably by the liver. TBG levels are increased fourfold to fivefold in affected individuals. Carrier females have intermediate serum TBG values (Larsen et al., 2008).

Familial Dysalbuminemic Hyperthyroxinemia

Familial dysalbuminemic hyperthyroxinemia is characterized by almost a 60-fold increase in the affinity of albumin for T_4 but not for T_3 . Mutations in the *ALB* gene (which encodes albumin) are inherited in an autosomal dominant manner (Larsen et al., 2008). The biochemical profile demonstrates increased serum T_4 concentrations but normal fT_4 , total serum T_3 , and TSH levels. Although binding of T_4 to albumin is increased, T_3 is less avidly bound, accounting for the preferential increase in serum T_4 concentration. Patients with this disorder are euthyroid with normal thyroid hormone production rates (Cartwright et al., 2009).

Diagnosis is confirmed by protein electrophoresis of serum containing labeled T_4 . The fraction of T_4 label associated with TBG, thyroid hormone binding by human serum prealbumin (TBPA), or albumin is measured. The amount of albumin-bound T_4 can be calculated and related to normal values. Measurement of TBG and TBPA concentrations is useful; antithyroid therapy is not necessary, and these measurements help avoid the misdiagnosis of hyperthyroidism (Stockigt et al., 1986).

Treatment of Hypothyroidism

Treatment of hypothyroidism relies on replacement with exogenous thyroid hormone. LT4 is the drug of choice because of its uniform potency and reliable absorption (Rose et al., 2006). Appropriate doses of synthetic T_4 produce normal serum levels of T_3 via peripheral conversion. The best guide to adequacy of therapy is periodic measurement of circulating levels of T_4 , fT_4 , and TSH. Treatment with LT4 should be started as soon as possible and no later than the first 2 weeks of life. History and physical examination are important in the follow-up evaluation, but mild hypothyroidism or hyperthyroidism cannot always be excluded on clinical grounds.

The usual starting dosage of thyroid hormone for hypothyroid infants is 10–15 $\mu\text{g}/\text{kg}$ per day, which approximates to 100 $\mu\text{g}/\text{m}^2$ per day. Infants with severe disease, as defined by a very low T_4/fT_4 concentration, should be treated with the highest initial dose, and those with mild to moderate hypothyroidism should be treated with a lower dose. If intravenous treatment is necessary, the dose should be no more than 80% of the oral dose. The aim of treatment is to keep the T_4 level in the upper half of the normal range, approximately 10–16 $\mu\text{g}/\text{dL}$ or the fT_4 level in the 1.4–2.3 ng/dL range, with the TSH level on the lower half of the normal range (0.5–2.0 mU/L), during the first 3 years of life. Recent studies have reported neurodevelopmental benefits of quick normalization of T_4 and fT_4 levels within 3 days of initiation of thyroid hormone therapy with high-dose treatment. Thyroid hormone requirements, however, quickly drop after 2 weeks, and therefore close monitoring of growth and development along with thyroid function tests is

necessary (Salerno et al., 2002; Selva et al., 2002). The treatment of each patient must be individualized. The adequate dosage of thyroid hormone in the first year usually ranges between 25 and 50 μg daily. Only LT₄ tablets should be used; currently there are no liquid formulations licensed by the US Food and Drug Administration. LT₄ suspensions prepared by individual pharmacists may lead to an unreliable dosage (Rose et al., 2006). The tablet is crushed and given orally in a small amount of liquid. Care should be taken to avoid concomitant administration of soy, fiber, calcium, or iron. The thyroid hormone–pituitary feedback setpoint is altered in rare infants with CH, and in such infants, serum TSH concentration remains elevated in the face of a normal or even elevated serum T₄ level (Fisher et al., 2000).

Infants with presumably transient hypothyroidism resulting from maternal goitrogenic drugs need not be treated unless the low serum T₄ and elevated TSH levels persist beyond 2 weeks of age. Infants with TRBAb-induced hypothyroidism may require treatment for as long as 6 months.

When infants with severe myxedema associated with fluid retention are being treated, potential complications should be kept in mind. Cardiac insufficiency caused by overtaxing of the myxedematous heart, through too rapid a mobilization of the myxedema fluid into the circulation, is well known in the adult. This complication in older children and adults is prevented by administration of a small dose of thyroid hormone at first, followed by gradual increase of the dose. However, infants generally tolerate a rapid restoration to the euthyroid state better than adults, and a prompt restoration of T₄ concentration to a normal value is important for the recovery of brain development and maturation. Nevertheless, excessive thyroid hormone therapy must be avoided, and the dose must be adjusted judiciously if there is evidence of severe myxedema, particularly of the heart.

After initiation of therapy with LT₄, the growth rate should accelerate. Any growth deficit is commonly restored within a few months. Bone age is a sensitive index of thyroid deficiency; however, radiographs are not routinely obtained in the newborn period. Overtreatment can induce tachycardia, excessive nervousness, disturbed sleep patterns, and other problems suggesting thyrotoxicosis. Excessive thyroid hormone administered over a long period can produce premature synostosis of cranial sutures and advancement of bone age.

During the first few years of life, patients should be monitored frequently: the first follow-up examination should occur 2 to 4 weeks after the start of LT₄ treatment. Subsequent evaluations should occur at least every 1 to 2 months during the first 6 months of life, every 3 months between 6 months and 3 years, and then twice a year until growth is completed (Box 98.1; LaFranchi, 2011). Evaluations should occur at more frequent intervals when adherence is questioned, abnormal values are obtained, or the dose of medication has been changed. Clinical observation should be supplemented with monitoring of the growth curve and T₄, fT₄, and TSH levels. Because poor adherence and nonadherence have major sequelae, the initial and ongoing counseling of parents is of great importance.

Patients with permanent CH (e.g., dysgenesis, dyshormonogenesis) require lifetime substitution therapy. After age 3 years, if there is uncertainty about whether the disease is permanent or transient or if the dose of LT₄ has not required an increase, discontinuation of LT₄ therapy for 4 to 6 weeks, with close monitoring of the TSH level, should distinguish transient from permanent CH. Recent reports indicate that treatment of CH is discontinued within 3 years in more than one-third of children with CH. This

•BOX 98.1 Management of Congenital Hypothyroidism

Initial Work-Up

Detailed history and physical examination
Referral to pediatric endocrinologist
Recheck serum TSH and FT₄ levels
Thyroid ultrasonography and/or thyroid scan (see text for recommendations)

Medications

LT₄: 10–15 $\mu\text{g}/\text{kg}$ by mouth once daily

Monitoring

Recheck serum FT₄ (or total T₄) and TSH
Two to 4 weeks after initial treatment has begun
Every 1–2 months in the first 6 months
Every 3 months between 6 months and 3 years of age
Every 6–12 months from 3 years of age to end of growth
Four weeks after a change in LT₄ dosage

Goal of Therapy

Normalize TSH and maintain T₄ and FT₄ in the upper half of the reference range

FT₄, Free thyroxine; LT₄, levothyroxine; T₄, thyroxine; TSH, thyroid-stimulating hormone.

is inconsistent with current guidelines; however, it remains unknown how many of the children in whom treatment was discontinued prematurely experience adverse effects or require continued treatment.

Hyperthyroidism

The overall incidence of neonatal hyperthyroidism is low. It occurs more commonly in pregnancies complicated by Graves disease. One percent of the offspring born to women with Graves disease have hyperthyroidism (Polak, 1998). The thyroid dysfunction in the fetus and newborn is associated with transplacental passage of TSH receptor–stimulating antibodies/TSIs. The mother may have active or inactive Graves disease. The hyperthyroidism is not related to transfer of maternal thyroid hormone. The antibodies stimulate the fetal and neonatal thyroid gland. It is generally a transient state that clinically resolves by 4 months of age with the clearance of maternal antibodies from the infant's circulation (Polak, 1998). Rarely, neonatal hyperthyroidism is caused by mutations in the genes that encode the TSH receptor or its mediators. These causes include activating mutations of the gene encoding the stimulatory G protein, as in McCune–Albright syndrome, or an activating mutation of the gene encoding the TSH receptor (Guerin et al., 2004; Chester et al., 2008).

In pregnancies complicated by maternal Graves disease, the fetal levels of TSI approximate those of the mother at 30 weeks of gestation. Therefore fetal thyrotoxicosis generally manifests itself in the third trimester as fetal tachycardia, fetal goiter, and intra-uterine growth retardation. Fetuses of mothers with TSI levels greater than 250% of the upper limit are at increased risk of thyrotoxicosis. Therefore these fetuses need to be monitored more closely (Zimmerman, 1999).

The clinical manifestations of Graves disease in the newborn include irritability, flushing, diarrhea, vomiting, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos. Thrombocytopenia, hepatosplenomegaly, jaundice, and

hyperviscosity syndrome have also been reported. If thyrotoxicity is severe and treatment is inadequate, arrhythmias, congestive heart failure, and death may occur. In some infants the onset of symptoms and signs may be delayed for as long as 8 to 14 days. Late onset of neonatal disease can occur for at least two reasons: (1) postnatal depletion of transplacentally acquired blocking doses of maternal antithyroid drugs and the abrupt increase in conversion of T_4 to active T_3 shortly after birth in the newborn and (2) the presence of maternal TRBAs, which can block the effect of TSH receptor–stimulating antibodies for several weeks (Zimmerman, 1999).

The diagnosis is confirmed by measurement of high levels of T_4 , fT_4 , and T_3 in postnatal blood. Umbilical cord blood values may be normal or near normal, whereas the levels at 2 to 5 days may be markedly increased; the serum TSH concentration is suppressed below normal levels. Neonatal Graves disease resolves spontaneously as maternal TSH receptor–stimulating antibodies in the newborn are degraded. The usual clinical course of neonatal Graves disease is 3–12 weeks.

Fetal thyrotoxicosis is treated by administration of antithyroid agents to the mother. Propylthiouracil (PTU) is recommended during pregnancy, because it is associated with a lower rate of fetal malformations than methimazole (MTZ). PTU crosses the placenta to inhibit the fetal production of excess thyroid hormone (Aslam and Inayat, 2008). Since the concentration of the drug in breast milk is very low, hyperthyroid mothers receiving antithyroid drugs may breastfeed their infants. Medical treatment of hyperthyroidism in the newborn period depends on the severity of the illness. The medications include iodide or antithyroid agents. Antithyroid agents inhibit thyroid hormone synthesis. Iodide rapidly inhibits hormone release.

Lugol's solution (5% iodine and 10% potassium iodide, containing iodine at 126 mg/mL) is given in a dose of one drop (8 mg iodine) three times daily. Antithyroid agents such as MTZ or carbimazole are administered in dosages of 0.5–1 mg/kg per day, divided, at 8-hour intervals. PTU is no longer recommended for use in children because of increasing rates of PTU-induced liver failure (Rivkees and Mattison, 2009). Propranolol can be given in a dosage of 2 mg/kg per day to decrease β -adrenergic symptoms and inhibit deiodination of T_4 to T_3 . A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodide can be increased by 50%.

More severe cases may require corticosteroids. Steroids suppress deiodination of T_4 to T_3 . Digoxin treatment can be used if cardiac failure is present. If hyperthyroidism persists (as in cases with a strong family history of Graves disease, an activating mutation of

the gene encoding the stimulatory G protein, or an activating mutation of the gene for the TSH receptor), ablative therapy such as thyroidectomy must be performed (Chester et al., 2008).

The treatment goal is to achieve a euthyroid state while avoiding hypothyroidism in the infant. Frequent monitoring to adjust MTZ doses is indicated. Another method to treat hyperthyroidism using antithyroid medication is to completely block the synthesis of thyroid hormone while replacing thyroid hormone.

Disorders of Carbohydrate Metabolism

DAVID WERNY, CRAIG TAPLIN, JAMES T. BENNETT, AND CATE PIHOKER

KEY POINTS

- Neonatal hypoglycemia requires diagnostic consideration and urgent management to prevent recurrent hypoglycemia and neurologic injury.
- Neonatal metabolism in the first few days of life reflects a transition from the passive glucose consumption of the fetus to the active regulation of glucose in a fasting neonate.
- Diagnosing the cause of hypoglycemia requires an evaluation of the hormonal and metabolic response to hypoglycemia. Patients with hyperinsulinemic hypoglycemia should be assessed for diazoxide responsiveness, and nonresponsive patients should have an evaluation to determine if the process is focal or diffuse.
- Diabetes diagnosed before 6 months of age is very likely to have a genetic cause.
- Patients with neonatal diabetes because of mutations in the ATP-sensitive potassium channel genes can be treated with oral sulfonylurea therapy in place of insulin therapy.

Glucose is the primary metabolic fuel for the neonatal brain, and maintenance of normal glucose levels in the serum and across the blood–brain barrier is essential for normal neurologic function and development. Hypoglycemia in the neonate therefore requires thoughtful diagnostic evaluation and urgent treatment to prevent injury to the central nervous system. The mechanisms underlying neonatal hypoglycemia are best understood as inadequate hormonal and metabolic responses to hypoglycemia occurring in the context of the necessary shift from fetal to neonatal glucose metabolism in the first few days of life. These pathways and disorders are the focus of the initial portion of this chapter.

Hyperglycemia in the neonate most commonly occurs in the context of a physiologic stressor such as sepsis with cortisol and catecholamine release, intravenous (IV) glucose infusion, and exogenous glucocorticoid administration combining to cause hyperglycemia. Rarely, genetic causes of hyperglycemia result in transient neonatal diabetes mellitus (TNDM) or permanent neonatal diabetes mellitus (PNDM), which is the focus of the latter portion of this chapter.

Fetal to Neonatal Transition and Energy Metabolism

Fetal glucose supply is dependent on maternal plasma levels and its diffusion across the placenta, with no evidence for the existence

of fetal gluconeogenesis, or a robust ability to adjust rapidly to maternal hypoglycemia (Menon and Sperling, 1988; Marconi et al., 1993; De Leon et al., 2014). Once the placental link is interrupted and glucose is no longer delivered continuously via the umbilical vein, the neonate must maintain normoglycemia and adequate cerebral glucose delivery despite minimal and sporadic enteral carbohydrate intake during the first 24–72 hours of life. Glucose homeostasis is accomplished in a manner generally similar to that in older children who fast: via secretion of the counterregulatory hormones—namely, cortisol, glucagon, growth hormone (GH), and catecholamines—and their actions at target tissues, in combination with the suppression of insulin secretion. In concert, these hormonal changes regulate four different metabolic systems: glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (Table 99.1). The end result is to facilitate normoglycemia until carbohydrate intake and absorption occur on a more regular basis.

In the first few hours of life, in response to decreased delivery of glucose, glucagon and catecholamine levels rapidly increase, and insulin level falls. This combination shifts metabolic activity from anabolism to catabolism and induces enzymes necessary for glycogenolysis (glycogen phosphorylase) and gluconeogenesis (pyruvate carboxylase and phosphoenolpyruvate carboxykinase) (Granner et al., 1983; Menon and Sperling, 1988; Girard, 1990). Glycogen breakdown plays the largest role in meeting glucose needs during the first 24 hours (approximately 50%) and causes a depletion of glycogen stores from 50 mg/g of liver at birth to less than 10 mg/g of liver at 24 hours of life (De Leon et al., 2014). Gluconeogenesis develops somewhat more slowly and is not fully active until 8–12 hours of life, providing 20%–30% of glucose needs in the first 24 hours (Girard, 1990; Kalhan et al., 2001).

Gluconeogenesis and lipolysis contribute to plasma glucose levels after 8–12 hours of life, with their role increasing as glycogen stores are depleted. Lipolysis produces glycerol, which can enter into the gluconeogenic pathways, and free fatty acids (FFAs) can be oxidized directly by some organs, including the heart, kidney, and skeletal muscle, but long-chain fatty acids cannot cross the blood–brain barrier (Patel and Kalhan, 1992). Importantly, partial oxidation of fatty acids in the liver via ketogenesis produces ketones such as β -hydroxybutyrate (BOHB) and acetoacetate, which the brain can metabolize. However, ketogenesis is impaired in the first 8–12 hours of life, coincident with the known transitional hypoglycemia of infancy discussed later (Stanley et al., 1979, 2015). The importance of gluconeogenesis, lipolysis, and fatty acid metabolism is highlighted in breastfed infants as the macronutrient profile of colostrum favors protein and fatty acids, compared with

TABLE 99.1 Genetic Causes of Hyperinsulinemic Hypoglycemia

| Inheritance | Molecular Defect | Chromosome | Histologic Appearance | Clinical Features | Treatment |
|-------------|---|-----------------|-----------------------|---|--|
| Sporadic | Paternally inherited <i>ABCC8/KCNJ11</i> mutation with somatic loss of heterozygosity | 11p15 | Focal | Macrosomia, moderate to severe hypoglycemia in the first few days to weeks of life | Poor response to diazoxide, local resection for focal and near-total pancreatectomy for the diffuse form |
| AR | <i>ABCC8/KCNJ11</i> (inactivating) | 11p15 | Diffuse | Macrosomia, onset in the first few days to weeks of life, family history or consanguinity may be present | Near-total pancreatectomy |
| AD | <i>ABCC8/KCNJ11</i> (dominant negative, inactivating) | 11p15 | Diffuse | Milder symptoms, may manifest themselves in late infancy | Usually responsive to diazoxide (Pinney et al., 2008) |
| AD | <i>GLUD1</i> (activating) | 10q23 | Diffuse | Modest hyperinsulinemia and hyperammonemia, onset usually >6 months | Diazoxide, restriction of leucine in the diet |
| AD | <i>GCK</i> (activating) | 7p13 | Diffuse | Modest hyperinsulinemia, onset usually >6 months | May respond to diazoxide |
| AR | <i>HADH</i> | 4q25 | Diffuse | Variable clinical presentation, abnormal acylcarnitine profile | Diazoxide |
| AD | <i>HNF4A</i> or <i>HNF1A</i> | 20q13 and 12q24 | Diffuse | Possible Fanconi tubulopathy. May have family history of MODY | Diazoxide |
| AD | <i>UCP2</i> | 11q13 | Diffuse | | Diazoxide |
| AD | <i>HK1</i> | 10q22 | Diffuse | Variable severity and penetrance | Diazoxide |
| AR | <i>PGM1</i> | 1q31 | | Congenital disorder of glycosylation. Bifid uvula, hepatopathy, hypogonadotropic hypogonadism, poor growth, myopathy, dilated cardiomyopathy (Tegtmeyer et al., 2014) | Galactose supplementation may be beneficial |

AD, Autosomal dominant; AR, autosomal recessive; MODY, maturity-onset diabetes of youth.

the relative carbohydrate predominance of mature human milk (Jenness, 1979).

Glucagon level continues to rise gradually over the first few days of life, coincident with the known gradual increase and stabilization of glucose levels that occur in normal infants by 48–72 hours of life (Lubchenco and Bard, 1971; Sperling et al., 1974).

The brain is the most metabolically active neonatal organ, and its demand for glucose is proportional to brain weight (Bier et al., 1977; Zeller and Bougneres, 1992). Glucose uptake and oxidation in the brain occur via insulin-independent facilitated diffusion through glucose transporter (GLUT) channels and is dependent on arterial blood glucose concentration. An in vivo study using rats (which are believed to have GLUT channels with similar kinetics to those of humans) showed that consumption of glucose in the brain outpaces its replacement via diffusion at an arterial concentration of 36 mg/dL (Choi et al., 2001). At this point cerebral blood flow increases markedly, presumably to prevent severe central nervous system glucose depletion and neurologic sequelae. The relatively large size of the neonatal brain, and its high metabolic demand, is associated with a twofold to threefold higher (per weight) hepatic glucose production than in adults. Conditions that interfere with hepatic glucose production therefore place the infant at risk of hypoglycemia, some of which are discussed briefly in this chapter, and others are discussed in Chapter 22.

In total, the combined counterregulatory response and insulin suppression are similar to the starvation response that occurs in older children, with two exceptions: (1) the additional complication that maternal factors and immaturity of the counterregulatory response can interfere with glucose homeostasis in the neonatal period and (2) the decrease in insulin production and release of glycogen stores are not as pronounced as in older children. These latter factors may explain the “transitional hypoglycemia” seen in normal newborns during the first 24 hours of life.

Transitional Neonatal Hypoglycemia

Plasma glucose values in the first few hours of life are frequently lower than accepted thresholds for normoglycemia in older children, a phenomenon known as *transitional neonatal hypoglycemia*. Serial measurements of glucose in the first few days of life in healthy, term appropriate for gestational age (AGA) infants demonstrate average values in the 50s to low 60s (mg/dL) (Lubchenco and Bard, 1971; Srinivasan et al., 1986). If normal is defined as within two standard deviations from the mean, the lower limit of normal may be as low as the high 30s to low 40s in the first few hours of life (Srinivasan et al., 1986; Hoseth et al., 2000). In support of this, Lubchenco and Bard (1971) showed that if feeding is delayed by 3–6 hours from birth, approximately 10% of healthy, term AGA infants will have glucose levels below 30 mg/dL.

• BOX 99.1 Signs of Neonatal Hypoglycemia**Autonomic**

Sweating
 Pallor
 Tachycardia
 Tachypnea
 Tremor
 "Jittery"

Neuroglycopenic

Hypotonia
 Lethargy
 Coma
 Seizure
 Weak suck
 Abnormal cry (weak, high pitched)

A recent review (Stanley et al., 2015) of the data available on transitional hypoglycemia shows that it is characterized by relative hyperinsulinism (HI) as indicated by hypoketosis and preserved glycogen release in response to glucagon (Stanley et al., 1979). An additional factor may be the time required for the enzymatic machinery of gluconeogenesis and glycogenolysis to become active in response to the rise in glucagon and catecholamine secretion after birth.

It is unknown whether the decline in glucose values or the relative HI seen with transitional hypoglycemia serves an adaptive function. The important diagnostic distinction is that the decline in glucose level is transient. Just 2 of the 374 newborns (0.5%) in the Lubchenco and Bard cohort had a glucose level below 50 mg/dL before feeding on day 3 or 4 of life.

Signs and Symptoms of Hypoglycemia

Neonates with hypoglycemia may have no detectable symptoms and may be identified incidentally only on measurement of blood glucose levels or in the monitoring of a high-risk infant. When symptoms occur, they may be seen in a progression due to initial counterregulatory hormone responses (such as adrenergic hormones as well as cortisol and GH) that result in symptoms referable primarily to the autonomic system (autonomic, or "neurogenic," symptoms and signs). When deficient glucose supply to the brain occurs, neurologic dysfunction is detectable and may be considered the symptom of "neuroglycopenia" (Box 99.1). However, the symptoms may be subtle and difficult to recognize clinically and may be accompanied by other, nonspecific symptoms such as apnea, cyanosis, temperature instability (especially hypothermia), and bradycardia.

It is difficult to define a consistent threshold in the neonate below which hypoglycemia produces the aforementioned symptoms and especially neuroglycopenia. One often-quoted study of 17 children showed changes in auditory evoked potentials below a whole blood glucose concentration of 47 mg/dL (2.6 mmol/L) but only included four neonates with hypoglycemia (aged 1–3 days) (Koh et al., 1988). In those four neonates, three had no clinical signs at the time of the abnormal recorded evoked potentials, and one was drowsy. The challenge of defining a true threshold is underscored in these four neonates given that one of them was asymptomatic with normal evoked potentials at a whole blood glucose level of 1.9 mmol/L (34 mg/dL) on day 1 of life, while another neonate was symptomatic at a whole blood glucose level of 2.5 mmol/L (45 mg/dL).

Monitoring of Blood Glucose

While symptomatic, prolonged hypoglycemia in neonates is a risk factor for cerebral injury and poorer neurodevelopmental outcomes,

• BOX 99.2 Maternal and Neonatal Conditions That Increase the Risk of Neonatal Hypoglycemia

Maternal Conditions

Diabetes (gestational or pregestational)
 Administration of drugs (β sympathomimetics, e.g., terbutaline, oral hypoglycemic agents)
 Intrapartum dextrose infusion
 Hypertension/preeclampsia

Neonatal Conditions

Prematurity
 Intrauterine growth restriction
 Hypoxia–ischemia
 Large/small for gestational age
 Sepsis
 Hypothermia
 Polycythemia
 Presence of syndromic features (microphallus, midline defects, Beckwith–Wiedemann syndrome)

the lower limit of normoglycemia in asymptomatic infants has been difficult to elucidate (Burns et al., 2008; Adamkin, 2016). This is complicated by the pattern of transitional hypoglycemia mentioned earlier, during which plasma glucose values may drop to levels considered very low for older children. Maternal and neonatal conditions with a high risk of hypoglycemia are well known, and it is common for newborn nurseries to have screening protocols for these infants (Box 99.2). Such protocols commonly result in the treatment of asymptomatic infants on the basis of point-of-care glucose values, with limited evidence available to define the optimal threshold that minimizes overtreatment while still preventing neuroglycopenia and neurologic damage.

Multiple definitions of the ideal asymptomatic treatment threshold with regard to long-term neurologic outcomes have been proposed: 47 mg/dL (Lucas et al., 1988), 45 mg/dL (Tin et al., 2012), 40 mg/dL (Kaiser et al., 2015), and 30 mg/dL (Kerstjens et al., 2012). It is unlikely that a single threshold exists, as the point at which neurologic injury occurs is likely patient and situation dependent and related to the availability of ketones and other substrates to the brain.

Recently, a prospective investigation into an appropriate glucose treatment threshold for infants was performed using a prospectively evaluated cohort of 404 infants of gestational age at least 35 weeks who were at risk of hypoglycemia (infant of diabetes mother, birth at <37 weeks' gestational age, birthweight <10th percentile or >90th percentile) (McKinlay et al., 2015). Infants also wore blinded continuous glucose monitoring systems to allow the investigators to evaluate them for outcomes related to subclinical hypoglycemia missed on the intermittent point-of-care checks. Infants were treated to maintain a blood glucose concentration of at least 47 mg/dL for at least the first 48 hours of life. Neurodevelopmental outcomes were then assessed at 2 years of age with the Bayley Scales of Infant and Toddler Development, third edition, and tests of executive and visual function. The study authors found no association between hypoglycemic episodes and neurosensory impairment and concluded that neonatal hypoglycemia was not associated with adverse neurologic outcome when treatment was aimed at maintaining a blood concentration of 47 mg/dL in these high-risk infants.

Recent Pediatric Endocrine Society guidelines make glucose threshold recommendations for infants who are at risk of

hypoglycemia but without a known risk of permanent hypoglycemic disorders, such as HI, hypopituitarism, or an inborn error of metabolism. Such neonates should have a treatment threshold of 50 mg/dL in the first 48 hours. On the basis of evidence that suggests average glucose values in normal neonates older than 48 hours of age are no different from those of older children, [Thornton et al. \(2015\)](#) suggest that these infants should demonstrate an ability to maintain glucose levels above 60 mg/dL during a 6–8-hour fast before discharge ([Thornton et al., 2015](#)).

For diagnostic work-up of hypoglycemia after 48 hours of age, we recommend a glucose threshold of 50 mg/dL for collection of a “critical sample” to assess the neonate for the counterregulatory hormone response, insulin level, acidosis, and the presence of important metabolic substrates such as BOHB, lactate, serum amino acids, and FFAs. Perhaps most importantly, a plasma glucose level should be obtained simultaneously to allow accurate interpretation of the critical sample, as the point-of-care test result may be artificially low.

Normoinsulinemic Hypoglycemia

Insulin's role in maintaining normoglycemia is paramount as its activity lowers serum glucose concentration via glucose uptake through insulin-sensitive GLUTs and represses the effects of counterregulatory hormones whose primary function during hypoglycemia is to increase serum glucose values. It is therefore relevant to divide a discussion of the causes of hypoglycemia by those that are associated with appropriate suppression of insulin during hypoglycemia (normoinsulinemic hypoglycemia) and those that are associated with inappropriate, elevated insulin levels at the time of hypoglycemia (hyperinsulinemic hypoglycemia) ([Box 99.3](#)).

Hypoglycemia in Premature and Small for Gestational Age Infants

Premature or small for gestational age (SGA) infants are at high risk of transient hypoglycemia because of immaturity of the metabolic pathways described earlier, exacerbated by inadequate stores of glycogen and triglycerides. The doubling of average fetal weight from 1700 g at 32 weeks to 3400 g at birth is largely due to the accrual of hepatic glycogen and adipose tissue fat stores, which then serve as important reserves of substrates for energy metabolism in the first few days of life. Hypoglycemia can also be caused by delayed maturation of enzymes necessary for gluconeogenesis. Premature infants can have markedly reduced glucose 6-phosphatase activity relative to term infants that may persist for months after birth ([Hume and Burchell, 1993](#)). There is also a lack of glucose level rise after administration of gluconeogenic precursors, which suggests impaired activity of the enzymes of gluconeogenesis ([van Kempen et al., 2003](#)). For these reasons, SGA and premature infants should be screened for asymptomatic hypoglycemia and supported with IV dextrose or nasogastric feeding until their hypoglycemia resolves. It is important to note that hypoglycemia in these infants may be multifactorial, as HI may be a contributing factor as well (discussed later).

Counterregulatory Hormone Deficiency

Hypopituitarism

Deficiencies of cortisol or GH, or their combined deficiency, in the neonatal period can cause hypoglycemia. Often these two deficiencies occur together in the context of hypopituitarism with

• BOX 99.3 Causes of Neonatal Hypoglycemia

Hyperinsulinemic

Transient:

- Infants of diabetic mothers
- Intrapartum dextrose infusion into mother
- Stress in peripartum/postnatal period: trauma, asphyxia, hypothermia
- Small for gestational age infants

ATP-sensitive potassium channel defects

GLUD1 activating mutation

HADH mutation

GCK activating mutation

HNF1A and *HNF4A* mutations

UCP2 mutations

HK1 mutations

Beckwith–Wiedemann syndrome

Fundoplication (dumping syndrome)

Hyperinsulinism in congenital disorders of glycosylation

β-cell adenoma—multiple endocrine neoplasia type 1

Normoinsulinemic

Transient:

Developmental immaturity in adaptation to fasting: prematurity, small for gestational age

Increased metabolic expenditure: sepsis, erythroblastosis fetalis, polycythemia

Maternal conditions: toxemia, administration of tocolytics (β sympathomimetics)

Hypopituitarism

Primary adrenal insufficiency

Inborn errors of metabolism

Glycogen storage disease

Disorders of gluconeogenesis

Defects in fatty acid catabolism and ketogenesis

Organic acidurias

Galactosemia

Hereditary fructose intolerance

adrenocorticotrophic hormone (ACTH) and GH deficiency. Infants with congenital hypopituitarism often have other signs of midline malformations, such as a midline cleft palate, nystagmus (optic nerve hypoplasia), seizures (holoprosencephaly), direct hyperbilirubinemia (thyroid hormone deficiency), or micropenis and undescended testes in a male (gonadotropin deficiency). Brain magnetic resonance imaging (MRI) may reveal the underlying cause of hypopituitarism, which may range from severe midline malformations such as alobar holoprosencephaly to more subtle abnormalities such as an isolated ectopic posterior pituitary bright spot or a hypoplastic pituitary gland.

Biochemical evaluation of hypopituitarism requires careful consideration in the first few months to year of life. Conventional stimulation tests used to diagnose GH deficiency in older children have been used in infants, but normal responses are not well established. The stimulation test believed to be safest for use in infants is the glucagon stimulation test, which causes a rapid rise then rapid fall in glucose level, placing the infant at risk of hypoglycemia. Therefore this testing should only be done under close monitoring, preferably in an intensive care unit setting ([Carillo and Bao, 2009](#)). As an alternative, taking into account normal physiologic processes in the perinatal period, there is evidence that a single random GH measurement in the first week of life can adequately diagnose GH deficiency ([Binder et al., 2010](#)). Using a post hoc defined threshold of 7 μg/L, Binder et al. demonstrated

a sensitivity of 100% and a specificity of 98% for the diagnosis of GH deficiency.

Similarly, standardized testing to diagnose adrenal insufficiency in the neonatal period is currently a matter of debate. Glucagon stimulation testing can be used to simultaneously assess a neonate for GH and ACTH deficiency but carries the risk of hypoglycemia mentioned earlier. The conventional ACTH stimulation test using Cortrosyn has been used in infants; however, the appropriate dose of 125 µg, 1 µg, or 15 µg/kg has not been well established, and physician preference differs. Importantly, infants with ACTH deficiency will not develop classic salt wasting with hyponatremia and hypokalemia because of intact aldosterone production and secretion, which is regulated not by the pituitary but by the renin–angiotensin system. Hyponatremia may occur but is less severe relative to primary adrenal insufficiency and is likely because of reduced free water clearance, for which both cortisol and thyroid hormone play a role.

An important consideration in patients with hypopituitarism is that thyroid hormone should not be replaced until adrenal insufficiency has been either treated or ruled out, as thyroid hormone replacement will increase the metabolism of cortisol and can precipitate an adrenal crisis if done in the context of undiagnosed adrenal insufficiency.

Isolated Adrenocorticotrophic Hormone Deficiency

Isolated ACTH deficiency is very rare and is associated with mutations in the genes responsible for the production and/or modification of the proopiomelanocortin (POMC) precursor polypeptide. The *TBX19* gene codes for T-box 19, which regulates transcription of the *POMC* gene in corticotrophs, and deficiency has been associated with adrenal insufficiency in infants (Vallette-Kasic et al., 2005). A low estriol level on the prenatal triple-marker screen may be a predictor of *TBX19* mutation and ACTH deficiency in general (Weintrob et al., 2006). Deletions of the *POMC* gene itself affect all POMC peptides, including α -melanocyte-stimulating hormone, resulting in red hair and fair skin, in addition to ACTH deficiency, with severe obesity developing within the first few months of life (Krude et al., 1998). Mutations in *PCSK1* result in impaired cleavage of ACTH from POMC, as well as several gut hormones. Deficiency results in severe neonatal diarrhea and failure to thrive and a high risk of ACTH deficiency as well as panhypopituitarism, including central diabetes insipidus (Martin et al., 2013).

Primary Adrenal Insufficiency

Congenital Adrenal Hyperplasia

Cortisol deficiency caused by disease of the adrenal gland (primary adrenal insufficiency) in infants is most commonly due to congenital adrenal hyperplasia (CAH). The most common form of CAH, 21-hydroxylase deficiency (incidence 1 in 10,000 to 1 in 15,000 annually), results in ambiguous, virilized genitalia in an XX infant because of overproduction of adrenal androgens synthesized from precursors upstream of the enzyme block. However, in a XY infant, CAH due to 21-hydroxylase deficiency is more subtle and may present only with hyperpigmentation of the skin, particularly of the scrotum. The classic presentation of hyponatremia, hyperkalemia, and severe dehydration because of the cortisol and aldosterone deficiency of primary adrenal insufficiency often does not develop until 7–10 days of life, so their absence in a newborn with hypoglycemia should not rule out this condition. Newborn screening for the 21-hydroxylase deficiency form of CAH is now widespread, and thus a diagnosis is often suspected early because of elevated

17-hydroxyprogesterone levels in newborn blood spot samples. Where hypoglycemia occurs in an infant, especially with any of the aforementioned features of salt wasting or ambiguous genitalia, confirmation of a normal 17-hydroxyprogesterone level should be sought. Treatment is with hydrocortisone and fludrocortisone for glucocorticoid and mineralocorticoid replacement, respectively, along with sodium chloride supplementation because of the low salt content of breast milk and most formulas.

More rare forms of CAH include 11 β -hydroxylase deficiency (1 in 100,000 or 1 in 5000 in Jews of Moroccan ancestry; Rosler et al., 1992) and the very rare 3 β -hydroxysteroid dehydrogenase deficiency (HSD). As with 21-hydroxylase mutations, 46,XX infants with 11 β -hydroxylase deficiency resulting in hypoglycemia will have ambiguous genitalia. They may also have hypertension due to excessive production of deoxycorticosterone, a potent mineralocorticoid located upstream of the 11 β -hydroxylase enzyme block. 3 β -HSD deficiency results in undervirilized male genitalia, due to deficient testosterone synthesis, but may be associated with virilized female genitalia due to elevated dehydroepiandrosterone levels. Mutations in steroidogenic acute regulatory protein impair the transfer of cholesterol into the mitochondria, disrupting the necessary first step of steroid synthesis, the conversion of cholesterol to pregnenolone. These patients have cortisol deficiency, almost always have aldosterone deficiency, and XY infants can have phenotypically female external genitalia because of impaired androgen synthesis (Meimaridou et al., 2013).

X-Linked Adrenal Hypoplasia Congenita

Dosage-sensitive sex reversal adrenal hypoplasia congenita region of the X chromosome (DAX-1; which is encoded by *NROB1*) is a transcription factor located on the short arm of the X chromosome (Xp21). It is expressed in adrenal, hypothalamic, pituitary, and hypothalamic tissues, but its gene targets are largely unknown (Suntharalingham et al., 2015). Mutations in *NROB1* result in underdevelopment or agenesis of the adrenal gland with the potential to cause severe adrenal insufficiency in infancy. In the first few weeks of life, males classically exhibit vomiting, severe dehydration leading to vascular collapse, and often hyperpigmentation. Some patients are more mildly affected and present later in childhood with more mild adrenal insufficiency. Patients later develop hypogonadotropic hypogonadism, manifesting itself as delayed pubertal development without elevation of gonadotropin levels. However, DAX-1 appears to have a direct role in gonadal development, as there is also a component of primary hypogonadism (Yu et al., 1998; Mantovani et al., 2006). Further implicating its role in gonadal development is the finding that duplication of *NROB1* causes sex reversal with female external genitalia and variable presence of müllerian structures in a 46,XY infant (Sukumaran et al., 2013). Adrenal hypoplasia congenita (AHC) is also seen as a part of Xp21 contiguous gene deletion syndrome, which occurs due to deletion of *NROB1* and nearby genes encoding glycerol kinase, and dystrophin. Affected patients have severe developmental delay and develop Duchenne muscular dystrophy in addition to the primary adrenal insufficiency secondary to AHC.

IMAGe Syndrome

IMAGe syndrome (intrauterine growth restriction, metaphyseal dysplasia, congenital adrenal hypoplasia, and genital anomalies) was first described in 1999 in three boys who exhibited severe adrenal insufficiency shortly after birth (Vilain et al., 1999). The affected infants also had skeletal abnormalities, micropenis, and hypogonadotropic hypogonadism. Linkage analysis and sequencing

in a five-generation family identified a likely causative gene mutation in the gene encoding cyclin-dependent kinase inhibitor 1C (*CDKN1C*) located on chromosome band 11p15 within an imprinted cluster of genes (Arboleda et al., 2012). Affected patients in the pedigree had maternally transmitted mutations, suggesting that imprinting silences the paternal allele of *CDKN1C*. *CDKN1C* is believed to have a role in inhibiting cell cycle progression, and causative mutations are suspected to be gain-of-function mutations. Mutations in *CDKN1C* have also been associated with Beckwith–Wiedemann syndrome (BWS) as well as Russel–Silver syndrome, demonstrating the importance of this gene in regulating growth (Eggermann et al., 2014).

Adrenocorticotrophic Hormone Resistance

Resistance to ACTH at the level of the adrenal gland causes a rare form of primary adrenal insufficiency with retained aldosterone secretion. Cortisol level is low, and ACTH level is elevated. Hyperpigmentation caused by excessive production of alpha-melanocyte-stimulating hormone (α -MSH) and stimulation of melanocortin 1 receptor can be present at birth or develop over time. Almost 50% of cases are due to autosomal recessively inherited mutations in the melanocortin 2 receptor (or ACTH receptor) gene (*MC2R*) and the melanocortin 2 receptor accessory protein gene (*MRAP*) (Meimaridou et al., 2013). Autosomal recessive mutations in the nicotinamide nucleotide transhydrogenase gene (*NNT*) caused ACTH resistance in three consanguineous families, presumably because of increased oxidative stress in the zona fasciculata (Meimaridou et al., 2013).

Adrenal Hemorrhage

Adrenal hemorrhage is a rare occurrence in neonates and rarely results in adrenal insufficiency even when it is confirmed radiographically, likely because adrenal hemorrhage occurs bilaterally in only 5%–10% of cases (Gyurkovits et al., 2015). Maternal diabetes, high birthweight, fetal acidemia, and birth asphyxia are associated with higher rates of adrenal hemorrhage.

Inborn Errors of Metabolism

The neonatal inborn errors of metabolism are covered extensively in Chapter 22, and the key pathways of metabolism are outlined in Fig. 99.1. Hypoglycemia resulting from these conditions often requires fasting for at least 4–6 hours, and therefore they are less likely to present with hypoglycemia in infancy. However, a few conditions can impact early fasting adaptation and therefore can present with hypoglycemia in the neonatal period.

Glycogen Storage Diseases

Many of the glycogen storage diseases (GSDs) become clinically apparent later in childhood; however GSD type 1 can present in neonates as it is associated with hypoglycemia after fasting for just 2–2.5 hours. GSD type 1 results from impaired function of glucose 6-phosphatase, the enzyme responsible for the final step of glycogenolysis and gluconeogenesis in which glucose is produced from glucose 6-phosphate (see Fig. 99.1). Patients have hepatomegaly due to accumulation of fat, as well as elevated serum lactate, lipids, lactate, and uric acid levels. Administration of glucagon 2–4 hours after a carbohydrate meal is helpful diagnostically as it causes a rise in lactate level but no rise in glucose level. Treatment is with frequent feeding as well as more slowly absorbed carbohydrates such as uncooked cornstarch, to help prolong fasting tolerance.

Defects of Fatty Acid Catabolism and Ketogenesis

Medium-chain acyl coenzyme A dehydrogenase (MCAD) deficiency is the most common disorder of fatty acid oxidation (1 in 17,000). Newborn screening for MCAD deficiency is widespread, and infants with MCAD deficiency are often detected on the basis of screening. Defects arise from autosomal recessively inherited mutations in the *ACADM* gene, and MCAD is responsible for the initial dehydrogenation of acyl coenzyme A molecules with a chain length between 4 and 12 carbon atoms. Patients exhibit metabolic decompensation after periods of fasting or exhibit illness, and the levels of C₆–C₁₀ fatty acids are increased on an acylcarnitine profile, particularly octanoylcarnitine. Hypoglycemia is often a late finding, but lethargy, coma, and severe neurologic injury can occur because of the additional lack of ketone bodies available to the brain. Presentation is typically between the age of 3 months and the age of 3 years (average 18 months), but presentation can occur in the first few weeks of life (Derks et al., 2006). Urea, ammonia, uric acid, and liver function test levels are often abnormally elevated as well in the context of a hepatic steatosis.

Galactosemia

Galactosemia is described in more detail in Chapter 22. It occurs because of mutations in one of three genes necessary to metabolize galactose to glucose: the genes encoding galactose 1-phosphate uridylyltransferase (*GALT*), galactokinase (*GALK1*), and uridine diphosphogalactose 4-epimerase (*GALE*). Hypoglycemia can be a clinical presentation of galactosemia, often in the context of the other classic features such as hepatomegaly, jaundice, failure to thrive, cataracts, and *Escherichia coli* sepsis (Hennermann et al., 2011; Karadag et al., 2013).

Hereditary Fructose Intolerance

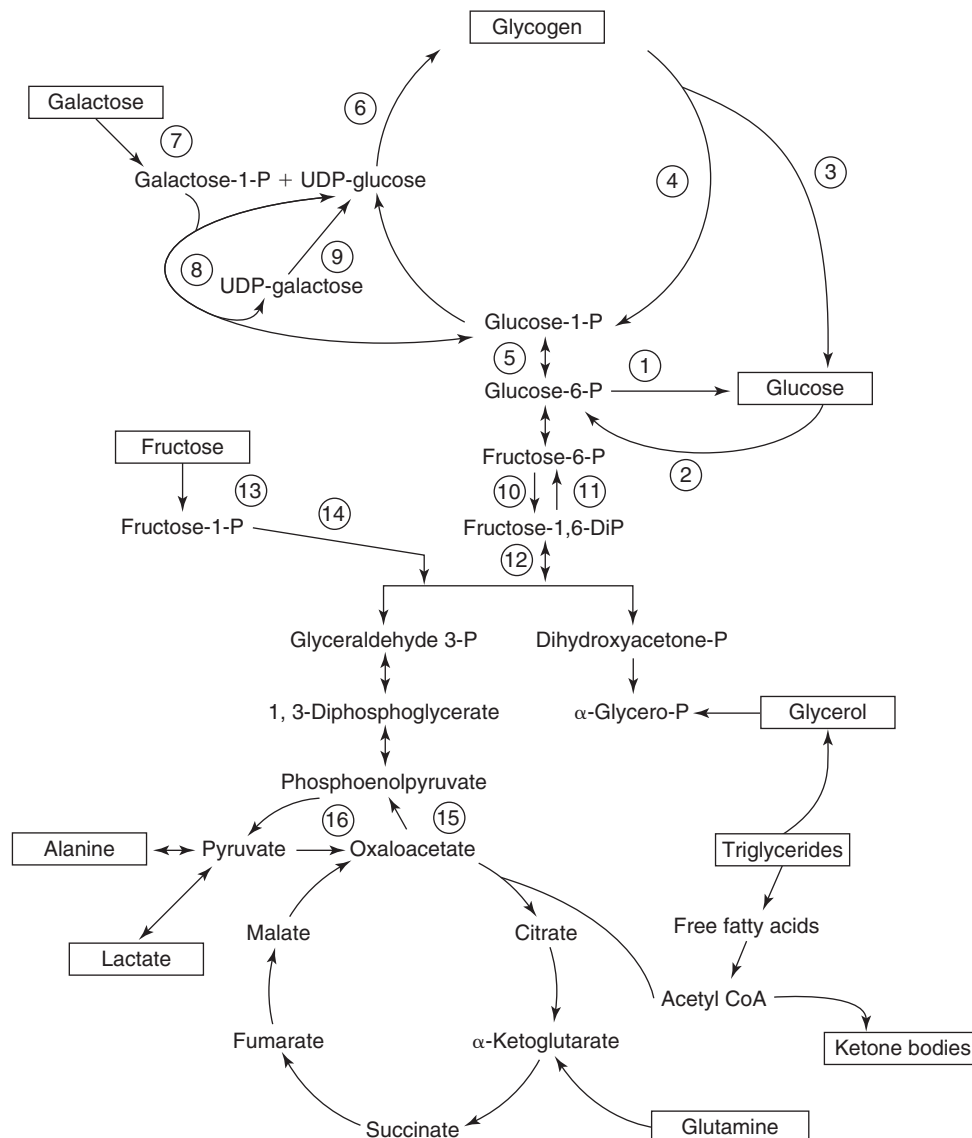

Hereditary fructose intolerance is due to mutations in the gene for aldolase B (*ALDOB*), which is responsible for metabolizing fructose 1-phosphate into substrates for gluconeogenesis. Vomiting, abdominal pain, acidosis, and hypoglycemia result after fructose or sucrose ingestion begins in infancy (Baker et al., 2015). The accumulation of fructose 1-phosphate leads to liver and kidney dysfunction, the extent of which is proportional to the degree of fructose consumption. Hypoglycemia at least partially results from impaired glycogenolysis in the liver, resulting in impaired response to glucagon (Van Den Berghe et al., 1973). Short-term treatment is with IV dextrose administration, and further organ injury can be prevented by avoidance of dietary fructose and high-fructose corn syrup.

Hyperinsulinemic Hypoglycemia

This section focuses on infants with hypoglycemia due to excessive insulin production. The causes include transient as well as permanent disorders of insulin secretion, and single-gene defects predominate in the permanent forms of HI (Table 99.1). A key management distinction among infants with HI is whether they can be treated with diazoxide and, if not, whether they have a focal or diffuse abnormality of pancreatic insulin regulation. Before the causes and management of HI are discussed, it is important to consider the physiology of insulin secretion from the pancreatic β cell.

Mechanism of Insulin Secretion

Depolarization of the pancreatic β cell leads to insulin secretion, and the most important regulator of membrane polarization in the pancreatic β cell is the adenosine triphosphate (ATP)–sensitive

potassium channel (K_{ATP} channel) (Fig. 99.2). The K_{ATP} channel is an octameric complex of two different subunits: (1) four inward-rectifying potassium channel subunits (Kir6.2 encoded by the *KCNJ11* gene) and (2) four regulatory sulfonylurea receptor subunits that surround the channel and help regulate the open or closed conformation of the channel (SUR1 encoded by the *ABCC8* gene). The channel is sensitive to the metabolic and energy state of the cell as manifested by the ATP/adenosine diphosphate (ADP) ratio in the cellular cytoplasm. Glucose enters the β cell via an insulin-independent glucose channel (GLUT2 encoded by the *SLC2A2* gene). If the glucose concentration is sufficiently

high, glucose is phosphorylated by galactokinase to glucose 6-phosphate, the first step of glycolysis and therefore the entry point for glucose in the metabolic pathways that produce ATP (see Fig. 99.1). The increased ATP/ADP ratio causes closure of the K_{ATP} channel, resulting in membrane depolarization. In response to depolarization, voltage-gated calcium channels open, and the increase in intracellular calcium concentration causes fusion of the insulin-containing vesicles with the cellular membrane and subsequent release of insulin extracellularly.

The essential role that the K_{ATP} channel plays in regulating insulin secretion is evidenced by the large number of mutations

Pancreatic β cell

• **Fig. 99.2** Mechanisms of insulin secretion by the β cell of the pancreas. Glucose transported into the β cell by insulin-dependent glucose transporter 2 (*Glut2*) undergoes phosphorylation by glucokinase and subsequent metabolism, resulting in an increase in the intracellular adenosine triphosphate (ATP)/adenosine diphosphate (ADP) ratio. The increase in the ATP/ADP ratio closes the ATP-sensitive potassium channel (K_{ATP} channel) and initiates the cascade of events characterized by an increase in intracellular potassium concentration, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (*GDH*) and by increasing the oxidation of glutamate, thereby increasing the ATP/ADP ratio and closure of the K_{ATP} channel. Mutations in the *HADH* gene, which codes for the mitochondrial enzyme L-3-hydroxyacyl coenzyme A dehydrogenase, which catalyzes the penultimate step in the fatty acid β -oxidation pathway, are also associated with hyperinsulinism (HI). Mutations in *HNF4A* cause multiple defects in glucose-stimulated insulin secretion. in both *KCNJ11* and *ABCC8* that cause either congenital HI (decreasing channel presence in the membrane or favoring the closed conformation) or neonatal diabetes mellitus (NDM; favoring the open channel conformation), both of which are discussed later in this chapter.

Diagnosis of Hyperinsulinism

Estimates of congenital HI differ widely depending on the study population but may be as high as 1 in 2500 in regions with high rates of consanguinity (Stanley, 2016). It is a common form of neonatal hypoglycemia, but the clinical features may be difficult to recognize and even missed until detection in later life or adulthood. However, infants with HI may have recognizable features of fetal hyperinsulinemia such as overgrowth and hypertrophic cardiomyopathy. The hypoglycemia is usually present early but can be initially difficult to distinguish from the transient neonatal hypoglycemia seen in the first few hours of life. However, the hypoglycemia may be immediately apparent as more severe and recalcitrant to early feeding. Confirming the diagnosis requires an index of suspicion on the part of the clinician and a search for historical and physical examination findings such as macrosomia and, potentially, signs suggestive of an underlying syndrome known to be associated with HI such as BWS, Kabuki syndrome, or

• BOX 99.4 Diagnostic Criteria for Hyperinsulinism Based on Critical Sample at Time of Hypoglycemia

- Insulin level $>2 \mu\text{IU/mL}$
- β -Hydroxybutyrate level $<1.8 \text{ mmol/L}$
- Free fatty acid level $<1.7 \text{ mmol/L}$
- Glucose rise $\geq 30 \text{ mg/dL}$ after glucagon administration
- Insulin-like growth factor-binding protein 1 level $\leq 110 \text{ ng/mL}$

Turner syndrome. As a state of excess glucose consumption, the normal physiologic rates of glucose supply are insufficient to maintain euglycemia, and thus a supraphysiologic glucose infusion rate (especially if $>10 \text{ mg/kg}$ per minute) in the hypoglycemic infant strongly suggests HI. Where hypoglycemia is recognized and confirmed, the confirmatory diagnosis of HI hinges on the critical detection of inappropriate hyperinsulinemia, including measurable insulin, and the metabolic markers of a persistent insulin effect, including suppressed FFA mobilization, hypoketosis, and a glycemic response to glucagon (Stanley and Baker, 1976; Stanley, 2016; Box 99.4).

However, important recent data from a retrospective review of infants with hypoglycemia have shown that some children with HI do not have detectable insulin at the time of hypoglycemia; of 28 individuals with congenital HI, only 23 had detectable insulin (median value $6.7 \mu\text{IU/mL}$), but in those where ketosis was measured, none had BOHB levels greater than 1.8 mmol/L (Ferrara et al., 2016). Importantly, bedside BOHB levels show good correlation with laboratory values, suggesting clinical utility in making a rapid diagnosis of HI. Similarly, infants without HI have FFA levels on average three times higher than in HI causes of hypoglycemia. While previous data suggested an FFA concentration cutoff of 0.5 mmol/L , these recent data suggest this misses many individuals with true HI and that an FFA concentration cutoff of less than 1.7 mmol/L provides sensitivity of more than 85%. Other biochemical data that are consistent with HI but may not yield results in as timely a manner as is ideal for rapid clinical confirmation include a C-peptide level of 0.5 ng/mL or higher and an insulin-like growth factor-binding protein 1 (which is suppressed by insulin) level of 110 ng/mL or lower.

These biochemical findings may be challenging to coordinate and collect in the setting of acute hypoglycemia, and so a diagnostic challenge using a provocative fast performed under controlled conditions may be required (Finegold et al., 1980). This should include frequent sampling of plasma glucose, insulin, BOHB, and FFAs. At a point where the glucose level falls below 2.8 mmol/L (50 mg/dL), the test can conclude with a glucagon challenge to test the glycemic response to an IV or intramuscular dose of glucagon (1 mg) followed by collection of glucose levels every 10 minutes for 40 minutes. A rise of 30 mg/dL or more in plasma glucose concentration is considered consistent with HI. This test has high specificity, and while some patients with subsequently confirmed HI in the aforementioned study did not achieve a rise in glucose concentration of 30 mg/dL or more, its sensitivity is greater than relying solely on the detection of serum insulin levels at the time of hypoglycemia. With a controlled provocative test as described herein, however, multiple markers of inappropriate hyperinsulinemia can be collected, and the clinician can thus arrive at a timely and correct diagnosis at the bedside. While the subsequent detection of urine ketones may provide adjunctive data, ketonuria does not exclude HI, and accurate diagnostic results are more likely to be

achieved in a timely fashion at the bedside by blood sampling (Wolfsdorf et al., 1984). These authors thus do not recommend routine reliance on urinary ketosis as a replacement for the protocol described.

Hypoglycemia in Infants of Diabetic Mothers

Transient hyperinsulinemic hypoglycemia is often associated with pregnancies affected by diabetes, including both gestational diabetes and permanent maternal diabetes. Infants are typically macrosomic and, despite high energy stores in the form of glycogen and fat reserves secondary to fetal hyperinsulinemia, hypoglycemia may persist for several days after disconnection from the high maternal glucose supply. This suggests a more persistent hyperinsulinemia, but it may resolve within the first few days to week of life. The severity of neonatal hypoglycemia in this setting is impacted by late pregnancy maternal glycemia, with avoidance of hyperglycemia reducing the severity of fetal hyperinsulinemic hypoglycemia (Andersen et al., 1985; Taylor et al., 2002). Neonates may require high rates of dextrose administration and/or frequent feedings, similar to patients with permanent congenital HI, but may successfully be weaned off high delivered substrate support judiciously during the first week or first 2 weeks of life.

Perinatal Stress and Transient Hyperinsulinism

While the well-described transitional hypoglycemia in normal newborns typically resolves within the first few hours to the first day of life, in stressed infants a persistent form of hypoglycemia may be seen (Hoe et al., 2006). The mechanism, similar to transitional hypoglycemia in healthy newborns, appears to be related to persistent HI, as ketogenesis and lipolysis remain suppressed. While somewhat unclear, it has been postulated that a lower glucose threshold for insulin secretion persists, given that insulin is a key fetal growth factor and thus its persistent secretion may confer a protective effect in the small or stressed neonate (Stanley, 2016). This may be seen in the context of perinatal asphyxia, preeclampsia, or SGA and may require interventions with early frequent feeding, medical therapy including diazoxide directed at the insulinemia, or continuous feeds to avoid the complications of hypoglycemia (Collins and Leonard, 1984; Collins et al., 1990; Thornton et al., 2015). For SGA infants with hyperinsulinemic hypoglycemia, diazoxide treatment is often required for as long as 6 months and has been reported to last as long as 22 months (Arya et al., 2013).

Mutations in the ATP-Sensitive Potassium Channel Genes *KCNJ11* and *ABCC8*

Mutations in the *KCNJ11* and *ABCC8* genes located on chromosome band 11p15.1 are the most common cause of permanent HI, accounting for about 40%–50% of cases in neonates, most of which concern *ABCC8* (de Lonlay et al., 2002; Dunne et al., 2004). Most commonly this is due to mutations that prevent channel formation, trafficking to the cell membrane, or insensitivity to the cellular ATP/ADP ratio. In the absence of a functional K_{ATP} channel, the β cell is permanently depolarized, leading to insulin secretion. Because diazoxide activity requires a functional channel present in the cell membrane, patients with *KCNJ11* or *ABCC8* mutations typically do not respond to diazoxide therapy.

The mechanism of inheritance of the K_{ATP} channel gene mutation strongly correlates with the extent of pancreatic involvement. Patients with two autosomal recessively inherited mutations will have diffuse

involvement of the pancreas, whereas patients with one paternally inherited mutation will have focal disease. The focal lesion arises from somatic loss of the maternal allele in a subpopulation of pancreatic cells, leading to focal unopposed expression of the mutated paternal allele, as well as unbalanced expression of imprinted genes that contribute to cellular hyperplasia (Dunne et al., 2004; Bellanne-Chantelot et al., 2010). Rarely, dominant-negative single allele mutations can result in diffuse disease. As described later in this section, the extent of pancreatic involvement directly impacts treatment. Patients with the focal histologic subtype can be cured by targeted surgical resection, whereas those with diffuse disease may require near-total pancreatectomy for definitive therapy.

Activating Mutation of the *GLUD1* Gene: Hyperinsulinemia–Hyperammonemia Syndrome

After mutations in *KCNJ11* and *ABCC8*, glutamate dehydrogenase (GDH) gene (*GLUD1*) mutations are the second most common cause of genetic HI. GDH is a mitochondrial matrix protein that converts guanosine diphosphate (GDP) to guanosine triphosphate (GTP), which in turn regulates amino acid and ammonia metabolism. Autosomal dominant, gain-of-function mutations increase the GTP/GDP ratio in the β cell, leading to closure of the K_{ATP} channel and subsequent depolarization and insulin secretion. Presentation is typically at between 4 and 12 months of age, but hypoglycemia can present in the first few days of life (De Lonlay et al., 2001). Leucine is an allosteric activator of GDH, causing hypoglycemia to worsen 30–90 minutes after a protein-rich meal. In addition to hyperinsulinemic hypoglycemia, patients also have elevated serum ammonia levels, although this is believed to have no clinical consequence and does not require therapy (De Leon et al., 2014). The hypoglycemia is diazoxide responsive, and carbohydrate loading is encouraged before protein-rich meals to prevent hypoglycemia. Patients may also develop generalized seizures, including absence epilepsy (Raizen et al., 2005).

HADH Mutation

Short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD; encoded by the *HADH* gene) is a mitochondrial enzyme responsible for β -oxidation of fatty acids, but patients with autosomal recessive mutations can have a presentation similar to those with HI–hyperammonemia (HA) syndrome (Clayton et al., 2001). This is due to SCHAD's additional role as a direct inhibitor of GDH activity via protein–protein interaction (Li et al., 2010). These patients share the same hypoglycemic sensitivity to protein loading as patients with HI–HA syndrome; however, they do not have HA and do not have an increased risk of seizure disorder. Affected patients can be identified by the presence of elevated serum 3-hydroxybutyrylcarnitine and elevated urine 3-hydroxyglutaric acid levels (Molven et al., 2004).

GCK Mutations

Glucokinase catalyzes the reaction of glucose to glucose 6-phosphate and serves as the “glucose sensor” of the pancreatic β cell. Dominant, activating mutations lower the glucose threshold for insulin secretion, causing hypoglycemia. Activating *GCK* mutations are usually de novo and not inherited from either parent, so the family history is typically negative. Affected infants are often large for their gestational age and can have severe hypoglycemia in the neonatal

period, but there is a wide spectrum of severity of presentation and hypoglycemia. Diazoxide therapy is effective in some cases, but pancreatectomy is required for some patients (Sayed et al., 2009).

HNF4A and HNF1A Mutations

Hepatocyte nuclear factor 4 α (HNF4 α) and hepatocyte nuclear factor 1 α (HNF1 α) are transcription factors expressed in hepatocytes, β cells, intestinal epithelial cells, and renal tubular cells, and are traditionally associated with maturity-onset diabetes of youth (MODY) types 1 and 3, respectively. Transcriptional regulation targets of HNF4 α and HNF1 α include each other, GLUT2, and possibly Kir6.2, but the exact cause of HI in infants is unclear (Stanescu et al., 2012). Some patients with neonatal HI due to *HNF4A* and *HNF1A* mutations develop diabetes years later in adolescence or young adulthood, consistent with MODY types 1 and 3. Diazoxide is effective as therapy for patients with hypoglycemia secondary to *HNF4A* and *HNF1A* mutations. *HNF4A* HI has also been described in combination with a renal Fanconi tubulopathy and hepatomegaly due to increased glycogen stores (Stanescu et al., 2012).

Other Genetic Causes of Hyperinsulinism

Autosomal dominant mutations in the uncoupling protein 2 gene (*UCP2*) have been shown in a few individuals with diazoxide-sensitive hyperinsulinemic hypoglycemia in infancy (Gonzalez-Barroso et al., 2008). *UCP2* was subsequently shown to regulate mitochondrial and cellular oxidation, and decreased *UCP2* activity is thought to increase the oxidation of glucose, thereby increasing the intracellular ATP/ADP ratio and increasing insulin secretion (Vozza et al., 2014).

With the cooperation of a four-generation pedigree of autosomal dominantly inherited congenital HI, Pinney et al. (2013) identified a new single gene cause of HI: *HK1*, which encodes hexokinase 1. Family members were variously affected, but all who were treated with diazoxide responded well.

Autosomal recessive mutations in the phosphoglucosyltransferase 1 gene (*PGM1*) cause a syndrome of abnormal protein glycosylation associated with a multifactorial hypoglycemia (Tegtmeyer et al., 2014). Patients demonstrate defects in glycogen breakdown as well as a postprandial hyperinsulinemia, both of which have been associated with hypoglycemia in infancy (Stanley, 2016). Other congenital disorders of glycosylation have been associated with HI, including phosphomannomutase 2 deficiency and mannose phosphate isomerase deficiency (Kapoor et al., 2009).

Beckwith–Wiedemann Syndrome

Patients with BWS have characteristic features including macrosomia, macroglossia, hemihypertrophy, ear pits, umbilical hernia, and a high risk of embryonal tumors. It results from epigenetic abnormalities in the imprinted 11p15.5 region. Most patients (85%) with BWS do not have a family history of the disorder. Children conceived by assisted reproductive technologies may be at increased risk of BWS and other imprinted disorders. Up to 50% of patients have hyperinsulinemic hypoglycemia with a wide spectrum of severity, most of which resolves in the first few days of life (DeBaun et al., 2000). The cause of HI in BWS is variable and may depend on the patient's specific genetic abnormality, sometimes including mutations in the *KCNJ11* gene or the *ABCC8*

gene (Kalish et al., 2016). Patients with BWS may respond to diazoxide; however, some patients require partial pancreatectomy.

After Fundoplication

Neonates undergoing fundoplication for gastric reflux or another reason are at risk of postprandial hypoglycemia related to dumping syndrome. Approximately 25% of neonates develop dumping syndrome after fundoplasty, most of which is identified in the first postoperative week (Calabria et al., 2011; Samuk et al., 1996). Hypoglycemia occurs 1–3 hours after a meal because of an exaggerated insulin response to early postmeal hyperglycemia, which is often detectable as well. Treatment is with slower gastric feeds, and sometimes continuous feeds are required. Treatment with uncooked cornstarch, pectin, octreotide, and acarbose has been attempted with various degrees of success as well (Calabria et al., 2011).

Differentiation Between Focal Adenomatous and Diffuse Pancreatic Hyperplasia

Patients with hyperinsulinemic hypoglycemia who are not responsive to diazoxide therapy should undergo specialized imaging to evaluate them for a focal pancreatic lesion that can be cured surgically. Positron emission tomography (PET) with [^{18}F]fluoro-L-dopa uses the fact that pancreatic β cells take up the radiolabeled L-dopa (Fig. 99.3). Simultaneous PET and MRI therefore provide visualization of the hyperactive β cells within the pancreas and allows the differentiation of focal and generalized hyperactivity (see Fig. 99.3). This distinction is important as it is far preferable to perform a curative focal resection rather than a “near-total” pancreatectomy, which has a more variable outcome ranging from continued HI to diabetes (Lord et al., 2015).

Approximately half of patients requiring surgery will have a focal lesion (De Lonlay et al., 1999, 2002). Such imaging is often successful in identifying the appropriate surgical management in those patients with HI refractory to medical management (Yang et al., 2012).

Management of Hyperinsulinemic Hypoglycemia

The goal of treatment is to minimize hypoglycemia frequency and duration to prevent impaired neurologic development. First-line treatment is with diazoxide, which opens the β -cell K_{ATP} channel, thereby decreasing insulin secretion. Common side effects include hypertrichosis and fluid retention, sometimes requiring diuretic use. Pulmonary hypertension has also been described in a small number of patients receiving diazoxide (Nebesio et al., 2007).

As mentioned earlier, not all hyperinsulinemic patients will respond to diazoxide (particularly those with K_{ATP} channel mutations), and second-line therapies include subcutaneous octreotide administration and glucagon infusion (Table 99.2). Octreotide is known to result in tachyphylaxis, causing diminishing efficacy of the medication. There is also a possible association with necrotizing enterocolitis, which requires special consideration in the neonatal population (Hawkes et al., 2016). Glucagon infusion is effective but not sustainable as a long-term treatment strategy because of the need either for IV infusion or for continuous delivery via a subcutaneous catheter. Continuous subcutaneous delivery systems

• **Fig. 99.3** (A) Frozen sections obtained from three pancreatic sites during surgery for a focal form of hyperinsulinism in the head. Specimens taken from tail and body show islets of Langerhans at rest with little cytoplasm, leading to crowded nuclei, whereas the focal form aspect from the head is that of multilobular involvement with local signs of β -cell hyperactivity: abundant cytoplasm and large, abnormal nuclei (toluidine blue stain; original magnifications $\times 200$ and $\times 100$). (B) Frozen sections obtained from three pancreatic sites during surgery for the diffuse form of hyperinsulinism. On each biopsy specimen, there is one islet showing hyperfunctional signs with abundant cytoplasm and irregular nuclei more than four times the size of the acinar nuclei nearby used as an internal control. The disease involves the whole pancreas and, in consequence, can be called *diffuse*, which does not mean that all islets are involved in the same manner (toluidine blue stain; original magnification $\times 200$). (Reproduced from Delonlay P, Simon A, Galmiche-Rolland L, et al. Neonatal hyperinsulinism: clinicopathologic correlation. *Hum Pathol*. 2007;38:387–399.)

TABLE 99.2

Drugs Used in the Management of Neonatal Hyperinsulinism

| Drug | Dose/Route | Mechanism of Action | Adverse Effects |
|--|---|--|---|
| Diazoxide | 5–20 mg/kg per d in three divided doses orally | Binds to SUR1 subunit, opens K_{ATP} channel | Fluid retention, hypertrichosis, rarely eosinophilia, leukopenia, hypotension |
| Chlorothiazide (in conjunction with diazoxide to decrease fluid retention) | 7–10 mg/kg per d in two divided doses orally | Synergistic response to diazoxide | Hyponatremia, hypokalemia |
| Octreotide | 5–25 μ g/kg per d in 6–8-hourly SC injections or IV infusions | Inhibits insulin secretion by binding to somatostatin receptors and inducing hyperpolarization of β cells, direct inhibition of voltage-dependent calcium channels | Anorexia, nausea, abdominal pain, diarrhea, tachyphylaxis |
| Glucagon | 1–20 μ g/kg per h, SC injection or IV infusion | Increases glycogenolysis and gluconeogenesis | Nausea, vomiting, paradoxical insulin secretion at high dose |

K_{ATP} , ATP-sensitive potassium; IV, intravenous; SC, subcutaneous.

have been described, but they are limited by crystallization of the glucagon and obstruction of the tubing (Mohnike et al., 2008). Sirolimus, a known cause of transplant-related diabetes, has also been used experimentally with some success (Senniappan et al., 2014).

Nutritional factors should also be considered, by increasing the carbohydrate content of feeds or by altering the length and frequency of feeding breaks. Families should be taught how to use a glucometer and to be vigilant for signs and symptoms of hypoglycemia. Parental education on the administration of glucagon is necessary before discharge.

Patients who require pancreatectomy have a high risk of future development of insulin-dependent diabetes and neurobehavioral

problems (Lord et al., 2015). Lord et al. (2015) recently reported the outcomes for 121 children with congenital HI treated with pancreatectomy, finding that 36% developed diabetes during long-term follow-up, and 20% of these patients developed diabetes in the immediate postoperative period. The risk of diabetes was associated with the percentage of pancreatectomy: 93% of those with diabetes had a 95% pancreatectomy or greater, while those without diabetes had a median 65% pancreatectomy. From parent-reported questionnaires, 48% had neurobehavioral concerns, including 21% of patients with psychiatric or behavioral concerns, 18% with speech delay, and 16% with learning disability. Quantitative measures of adaptive behavior were abnormal in 27% of patients.

The finding that these neurodevelopmental outcomes were similar for the focal and diffuse groups suggested to Lord et al. that a shared exposure to recurrent hypoglycemia in the neonatal period may be causative.

Hyperglycemia in the Neonate

Insulin is a critical mediator of fetal growth, and therefore infants with hyperglycemia due to persistent insulin deficiency are almost universally born SGA and have a history of intrauterine growth restriction. It is thought that the autoimmune process leading to β -cell destruction takes at least 6 months to manifest itself, and therefore the classic, autoimmune-mediated type 1 diabetes earlier than 6 months of age does not occur, with the notable exception of immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome-related diabetes (Iafusco et al., 2002). Persistent hyperglycemia that meets the criteria for diabetes (glucose level >125 mg/dL fasting or >200 mg/dL) in an infant younger than 6 months strongly suggests a monogenic cause, and genetic testing is positive in at least 80% of cases (De Franco et al., 2015). About 50% of infants with diabetes in the first few months of life will have resolution by 1–2 years of age (TNDM), but a significant portion of these patients will have relapse of diabetes later in childhood or adolescence (von Muhlendahl and Herkenhoff, 1995; Rubio-Cabezas et al., 2014). A family history of early adulthood-onset diabetes mellitus, perhaps reported as or assumed initially to be type 1 diabetes mellitus, type 2 diabetes mellitus, or MODY, can suggest an inherited abnormality of insulin secretion, but a family history is not present in 70% of molecularly confirmed cases (De Franco et al., 2015). Elucidation of the specific genetic mutation has immediate implications for treatment, as those with mutations in the *KCNJ11* or *ABCC8* genes, which encode the components of the K_{ATP} channel, are best treated with orally administered sulfonylurea rather than insulin.

Transient Stress-Related Hyperglycemia

More commonly, neonatal hyperglycemia is transient and caused by physiologic stress such as sepsis or other acute illness, particularly in infants receiving continuous IV dextrose infusions (Mittal et al., 2013; Box 99.5). Cortisol and catecholamines secreted during acute illness increase gluconeogenesis, glycogen breakdown, and insulin resistance, all of which increase the plasma glucose concentration. Hyperglycemia will resolve as the neonate's overall clinical status improves and as glucose infusion rates are minimized to the

lowest necessary amount. Insulin infusions may be necessary to control hyperglycemia in the short term.

Genetic Causes of Neonatal Diabetes

NDM is a genetically heterogeneous disease, with 22 known genetic subtypes. The different types of NDM differ widely in their prognosis, from mild self-resolving hyperglycemia to permanent forms associated with severe neurodevelopmental features. Some types of NDM respond to sulfonylureas, while others do not. Thus early referral for genetic testing should be made as soon as a clinical diagnosis of NDM is made. It is important to recognize that the absence of a family history does not exclude a genetic cause, as most NDM-causing mutations arise spontaneously (De Franco et al., 2015).

Transient Neonatal Diabetes Mellitus Due to Chromosome Band 6q24 Anomalies

Most patients (70%) with TNDM have an abnormality of the imprinted region of chromosome band 6q24. Within this imprinted region are two genes, *PLAGL1* and *HYMAI*, that share a promoter. This promoter is differentially methylated depending on the parent of allelic origin. In the normal situation, only the paternally inherited allele is expressed, while the maternally inherited allele is methylated and not expressed. Situations that lead to a relative increase in the expression of *PLAGL1* and *HYMAI* cause TNDM. These include paternal uniparental disomy, duplication of 6q24 on the paternal allele, or hypomethylation of the maternal allele, producing inappropriate *PLAGL1* and *HYMAI* expression from the maternal allele. The mechanism by which overexpression of *PLAGL1* and *HYMAI* leads to TNDM is not fully understood. A second, nonimprinted promoter also controls *PLAGL1* expression, which has led to the hypothesis that the postnatal remission of TNDM is due to a switch over to this nonimprinted promoter postnatally. This form of TNDM resolves at a median age of 3 months, but in about half of patients, diabetes will reappear during adolescence. Management is with subcutaneous insulin therapy until remission. Associated clinical features include macroglossia (50%), umbilical hernia (25%), facial dysmorphism (20%), cardiac and renal anomalies (9%), and hand anomalies (8%) (Docherty et al., 2013).

Transient Neonatal Diabetes Mellitus Due to ATP-Sensitive Potassium Channel Gene Mutations

About 25% of patients with TNDM have normal methylation at 6q24. Most of these 6q24-normal TNDM patients have heterozygous activating mutations in either *KCNJ11* or *ABCC8*, which encode the two components of the K_{ATP} channel as described earlier. Activating mutations in these same genes can also cause PNDM (see later). Although some studies have suggested that TNDM-causing mutations are functionally less severe than PNDM-causing mutations, some mutations in *KCNJ11* have been reported in both PNDM patients and TNDM patients, so an absolute genotype–phenotype correlation may not exist (Ashcroft, 2005; Gloyn et al., 2005). Compared with 6q24-associated TNDM, infants with K_{ATP} channel-associated TNDM have higher birthweight, later diagnosis, later remission, and earlier relapse of hyperglycemia (Flanagan et al., 2007). No significant clinical differences have been noted between *KCNJ11* and *ABCC8*-related TNDM, both of which respond favorably to sulfonylureas.

• BOX 99.5 Differential Diagnoses of Neonatal Hyperglycemia

Common Causes

Excessive intravenous glucose infusion
Impaired glucose homeostasis in preterm/sick/small for gestational age infants
Sepsis
Stress
Corticosteroids

Rare Causes

Transient neonatal diabetes
Permanent neonatal diabetes

Additional Genetic Causes of Transient Neonatal Diabetes Mellitus

Homozygous mutations within the promoter of the insulin gene (*INS*) have been reported in four unrelated TNDM patients (Garin et al., 2010). These mutations involve DNA elements within the promoter that serve as binding sites for neurogenic differentiation 1 (NEUROD1) and Gli-similar (GLIS)3, two transcription factors that are rare genetic causes of PNDM (see later). Promoter mutations within the *INS* gene can also cause PNDM. Even within the same family, the same *INS* promoter mutation (c.-331C>G) has been reported to cause TNDM in some individuals and PNDM in others. The reason for this variability is unknown.

Homozygous mutations in the gene *SLC2A2*, encoding GLUT2, which transports glucose into the β cell, have been reported in four unrelated patients with TNDM; the parents were first cousins in three of these patients (Sansbury et al., 2012). Biallelic mutations in *SLC2A2* also cause Fanconi–Bickel syndrome (FBS), whose features include renal Fanconi syndrome, poor growth, hepatomegaly, and impaired utilization of glucose and galactose (Santer et al., 2002). More than 95% of patients with biallelic *SLC2A2* mutations have symptoms of FBS without evidence of NDM, but the reason for this is unknown.

Nonsyndromic Causes of Permanent Neonatal Diabetes Mellitus

Infants with NDM without evidence of remission in the first year or first 2 years of life are classified as having PNDM. The most common cause of PNDM is heterozygous, activating mutations in the K_{ATP} channel subunit genes *KCNJ11* and *ABCC8* (more commonly *KCNJ11*), accounting for almost half of all patients with PNDM (Gloyn et al., 2004; Babenko et al., 2006). These mutations decrease the K_{ATP} channel's sensitivity to the cellular ATP concentration, keeping the channel inappropriately open and inhibiting insulin secretion. Twenty percent of individuals with PNDM due to *KCNJ11* mutations will also have developmental delay, epilepsy, and neonatal diabetes (DEND) syndrome (Clark et al., 2010). There are clear genotype–phenotype correlations within the *KCNJ11* gene, with some mutations being associated with DEND syndrome and others being associated only with PNDM. Patients with PNDM due to mutations in *KCNJ11* and *ABCC8* typically respond well to sulfonylureas. Some neurologic features of DEND syndrome have also been reported to respond to sulfonylureas, highlighting the importance of the K_{ATP} channel in neuronal cells (Pearson et al., 2006).

Mutations within *INS* are also a common cause of PNDM and are found in approximately 10% of patients with PNDM. *INS* mutations can be homozygous (more common among offspring of consanguineous relationships) or heterozygous, but in both cases the mutations lead to inadequate production of insulin (Edghill et al., 2008; Garin et al., 2010; De Franco et al., 2015).

Rarer genetic causes of nonsyndromic PNDM include biallelic inactivating mutations in *GCK* (which encodes glucokinase) and *PDX1* (Bennett et al., 2011; De Franco et al., 2013). Glucokinase serves as the “glucose sensor” of the β cell, converting glucose into glucose 6-phosphate. *PDX1* encodes a transcription factor necessary for the formation of the pancreas in utero. Heterozygous mutations in *GCK* are a relatively common cause of MODY, accounting for 20%–50% of MODY patients. Therefore *GCK* mutations should be strongly considered in patients with PNDM who have a family history of MODY, mild fasting hyperglycemia, or gestational

diabetes in a nonobese mother. Some patients with homozygous mutations of *PDX1* have pancreatic agenesis, producing exocrine insufficiency in addition to PNDM, but in some *PDX1* mutation patients, pancreatic exocrine function is intact (De Franco et al., 2013).

Syndromic Causes of Neonatal Diabetes Mellitus

In addition to the genes described earlier, there are 17 other known genetic causes of NDM, which are typically considered “syndromic” because they are often associated with other, nonendocrine features. Although some syndromic forms of NDM present with other features (e.g., congenital heart defects), diabetes is often the initial presentation, making early genetic diagnosis helpful as it can guide management and necessary screening. For example, patients with biallelic mutations in *EIF2AK3* have Wolcott–Rallison syndrome, which usually presents with NDM, while other features (skeletal dysplasia, developmental delays, and liver dysfunction) do not develop until later. A quarter of NDM patients whose parents are consanguineous have Wolcott–Rallison syndrome, making it the most common cause of PNDM among this group of patients. The remaining syndromic causes of NDM are listed in Table 99.3. Because of the large number of genetic causes of NDM, sequencing of multiple genes in parallel is typically the most efficient diagnostic approach.

Treatment of Neonatal Hyperglycemia

Treatment of hyperglycemia in the neonatal period is dictated by the clinical scenario and the results of genetic testing when available. Transient hyperglycemia is best managed by treatment of the underlying cause (e.g., sepsis). In addition to close monitoring of glucose levels, exogenous glucose administration can be decreased to approximately 3 mg/kg per minute. If necessary, insulin treatment can commence, starting with a low-dose insulin infusion (e.g., 0.03 units/kg per hour).

Treatment of NDM requires insulin, at least until a genetic diagnosis is made. For those with a mutation in 6p24, insulin requirements usually drop quite quickly, and treatment is often discontinued by 12 weeks of age. Hyperglycemia may recur with intercurrent illness and then recurs in more than half of children, generally at the time of puberty.

Infants with an identified mutation in *KCNJ11* or *ABCC8* can be treated with sulfonylureas. Generally it is best to gradually decrease insulin dosing as sulfonylurea treatment is initiated. Sulfonylurea dosing tends to be higher than typically used in adults. While more than 90% of those with a *KCNJ11* or *ABCC8* mutation can successfully transition from insulin to sulfonylurea and maintain near-normal glycemic control, the factors associated with sulfonylurea failure are the specific genetic mutation and longer duration of diabetes (Babiker et al., 2016). Treatment with sulfonylureas is not only effective in achieving euglycemia but has also led to improvements in neurologic status for patients with DEND syndrome; this appears to be secondary to improved cerebellar perfusion (Fendler et al., 2013).

Acknowledgments

We thank the authors of the chapter from the ninth edition (Vandana Jain, Ming Chen, and Ram K. Menon), whose work was the starting point for our chapter.

Craniofacial Malformations

KELLY N. EVANS, ANNE V. HING, AND MICHAEL L. CUNNINGHAM

KEY POINTS

- Craniofacial malformations can impact swallowing, breathing, hearing, vision, speech, and development and for some neonates can result in life-threatening airway compromise.
- Early recognition and assessment of craniofacial conditions that include appropriate diagnostic studies, identification of associated health concerns, and family education can have a positive impact on the care of the newborn.
- Timely referral of the newborn with a craniofacial condition for multidisciplinary craniofacial team care is an important step in the provision of coordinated medical and surgical management.

The neonatologist is often the first point of contact for a child born with a craniofacial malformation. Abnormalities of the face and head can be distressing to a new parent, who is immediately wondering, “Is my child going to look, feel, and develop normally?” Having a basic understanding of the relationship between craniofacial abnormalities and feeding, breathing, hearing, vision, speech, and overall development will help the neonatologist begin to counsel a family. Airway compromise is well described in multiple craniofacial syndromes, and early identification can be lifesaving. Prompt recognition of a constellation of anomalies pointing toward a syndrome or diagnosis will result in better targeted evaluations and therapies for that patient. (Tables 100.1–100.2 contain a concise presentation of potential intensive care unit [ICU] issues that may be encountered with certain craniofacial malformations and syndromes.) This chapter highlights the most relevant craniofacial malformations that a neonatologist will encounter. We describe here the epidemiology, genetics, diagnosis, phenotype, and potential ICU issues as well as basic management recommendations to help guide the neonatologist in caring for an infant with craniofacial malformations.

Micrognathia/Robin Sequence

Epidemiology

The triad of micrognathia, glossoptosis, and airway obstruction, originally described in 1923 by Pierre Robin, is known as *Robin*

sequence (RS) or *Pierre Robin sequence*. Whether cleft palate is an obligatory feature of RS is debatable. Approximately one-quarter of infants with cleft palate (CP) were found to have RS in a multisite, population-based, case-control study (Genisca et al., 2009). The tremendous heterogeneity and lack of uniformly accepted diagnostic criteria for, or definitions of, RS make it challenging to know the true prevalence. However, estimates of birth prevalence range from 1 in 8500 to 1 in 14,000 births (Bush and Williams, 1983; Printzlaun and Andersen, 2004).

Phenotype

RS is an etiologically and phenotypically heterogeneous disorder. More than half of children with RS have an associated syndrome, with Stickler syndrome being the most common. While there is great variation in severity, RS is characterized by the following phenotypic features: micrognathia (small and symmetrically receded mandible), glossoptosis (tongue of variable size falls backward into the postpharyngeal space), and resultant upper airway obstruction, often with a cleft palate (Breugem et al., 2016; Fig. 100.1A–B). Caouette-Laberge et al. (1994) described CP (U-shaped CP more common than V-shaped CP) in 90% of 125 individuals with RS. Infants with RS often have airway obstruction, feeding difficulties, and challenges gaining weight, and they may have associated anomalies, including hypotonia and limb reduction defects. Congenital heart defects are present in up to 25% of babies with RS who die in early infancy (Hennekam et al., 2010a). It has been reported that a portion of individuals with RS experience developmental delay, cognitive impairment, and poorer school achievement; overall morbidity and mortality are higher in syndromic RS or RS with associated anomalies compared with isolated RS (Caouette-Laberge et al., 1994; Persson et al., 2013). Clinical judgment can be made about whether the patient represents “isolated RS,” “RS plus,” or a syndromic form of RS, and the diagnostic work-up should include investigation of the common associated anomalies and syndromes (Tan et al., 2013; Gomez-Ospina and Bernstein, 2016).

Intensive Care Unit Concerns

In infants with RS the tongue is displaced toward the posterior pharyngeal wall or up into the cleft, resulting in upper airway

**TABLE
100.1****Craniofacial Syndromes Commonly Associated With Cleft Lip and/or Cleft Palate**

| Syndrome | Phenotype | ICU Issues | OMIM |
|---|--|--|--|
| Robin sequence ^a | Micrognathia, glossoptosis with upper airway obstruction, cleft palate | Airway obstruction, feeding difficulties | na |
| Stickler syndrome ^a | Cleft palate, micrognathia, glossoptosis (Robin sequence), high myopia, risk of retinal detachment and blindness, midface hypoplasia, hearing impairment, arthropathy, pectus, short fourth and fifth metacarpals | Airway obstruction, feeding difficulties | 180300, 604841, 184840, 614134, 614284 |
| 22q11.2 deletion syndrome (velocardiofacial syndrome, DiGeorge syndrome) ^a | Cleft palate and submucous cleft palate, small mouth, myopathic facies, retrognathia, prominent nose with squared-off nasal tip, hypoplastic nasal alae, short stature, slender tapering digits | Cardiac anomalies, airway obstruction, feeding difficulties, aspiration | 192430, 188400, 611867 |
| Opitz oculogenitoharyngeal syndrome (Opitz BBB/G syndrome) ^a | Hypertelorism, telecanthus, cleft lip and/or palate, dysphagia, esophageal dysmotility, laryngotracheoesophageal cleft (aspiration), hypospadias, bifid scrotum, cryptorchidism, agenesis of the corpus callosum, congenital heart disease, mental retardation | Laryngotracheoesophageal clefting (stridor, feeding difficulties, choking, aspiration) | 145410, 300000 |
| Pallister–Hall syndrome ^a | Cleft palate, flat nasal bridge, short nose, multiple buccal frenula, microglossia, micrognathia, malformed ears, hypothalamic hamartoblastoma, hypopituitarism, postaxial polydactyly with short arms, imperforate anus, genitourinary anomalies, intrauterine growth restriction | Laryngotracheoesophageal clefting (stridor, feeding difficulties, choking, aspiration), panhypopituitarism | 146510 |
| <i>IRF6</i> -related disorders (including Van der Woude and popliteal pterygium syndrome) | Cleft lip with or without cleft palate, cleft palate only, lower lip pits or cysts, ankyloglossia; popliteal pterygium syndrome will also have popliteal pterygia, bifid scrotum, cryptorchidism, finger and/or toe syndactyly, abnormalities of the skin around the nails, syngnathia and ankyloblepharon | Not anticipated | 119300, 119500 |
| CHARGE syndrome ^a | Coloboma of the eye, heart malformations, choanal atresia, growth retardation, genital anomalies, ear abnormalities and/or deafness, facial palsy, cleft palate, dysphagia | Airway obstruction in bilateral choanal atresia, cardiac anomalies, feeding difficulties, aspiration | 214800 |
| Smith–Lemli–Opitz syndrome ^a | Cleft palate, micrognathia, short nose, ptosis, high square forehead, microcephaly, hypospadias, cryptorchidism, ventricular septal defect, tetralogy of Fallot, hypotonia, mental retardation, postaxial polydactyly, 2–3 toe syndactyly, defect in cholesterol biosynthesis | Cardiac anomalies, airway hypotonia, and airway obstruction | 270400 |
| Ectrodactyly, ectodermal dysplasia, and clefting syndrome | Cleft lip and/or palate, split-hand/split-foot, ectodermal dysplasia (sparse hair, dysplastic nails, hypohidrosis, hypodontia), genitourinary anomalies | Not anticipated | 129900, 604292, 129400 |
| Ankyloblepharon, ectodermal dysplasia, and clefting syndrome | Cleft lip with or without cleft palate, cleft palate only, intraoral alveolar bands, maxillary hypoplasia, ankyloblepharon (eyelid fusion), ectodermal dysplasia (sparse hair, dysplastic nails, hypohidrosis, anodontia) | Not anticipated | 106260 |
| Orofaciodigital syndrome | Median cleft of upper lip, cleft palate, accessory oral frenula, lobulated tongue with hamartomas, broad nasal root, small nostrils, syndactyly, brachydactyly, postaxial polydactyly, polycystic renal disease, agenesis of the corpus callosum | Not anticipated | 311200 |
| Kabuki syndrome ^a | Cleft palate, arched eyebrow, long palpebral fissures, eversion of lateral third of lower eyelid, brachydactyly, short fifth metacarpal, cardiac anomalies, postnatal growth deficiency/dwarfism, mental retardation | Cardiac anomalies | 147920, 300867 |
| Fryns syndrome ^a | Cleft lip with or without cleft palate, micrognathia, coarse facies, diaphragmatic hernia, distal limb hypoplasia, malformations of the cardiovascular, gastrointestinal, genitourinary, and central nervous systems | Congenital diaphragmatic hernia, pulmonary hypoplasia; cardiac anomalies | 229850 |

**TABLE
100.1****Craniofacial Syndromes Commonly Associated With Cleft Lip and/or Cleft Palate—cont'd**

| Syndrome | Phenotype | ICU Issues | OMIM |
|---|--|--|------------------------|
| Miller syndrome (postaxial acrofacial dysostosis) ^a | Cleft palate (more than cleft lip), malar and mandibular hypoplasia, downslanting palpebral fissures, lower eyelid coloboma, microtia/atresia, conductive hearing loss, postaxial limb deficiency, absent fifth digit | Airway obstruction | 263750 |
| Treacher Collins syndrome (mandibulofacial dysostosis) ^a | Cleft palate, malar and mandibular hypoplasia, downslanting palpebral fissures, lower eyelid coloboma (missing medial lower eyelid lashes), microtia/atresia, conductive hearing loss | Airway obstruction | 154500, 613717, 248390 |
| Aarskog syndrome (faciodigitogenital syndrome) | Hypertelorism, widow's peak, ptosis, downslanting palpebral fissures, strabismus, maxillary hypoplasia, broad nasal bridge with anteverted nostrils, occasional cleft lip and/or palate, floppy ears, brachydactyly, clinodactyly, joint laxity, shawl scrotum | Not anticipated | 100050 |
| Wolf-Hirschhorn syndrome (4p deletion syndrome) ^a | Cleft lip and palate, coloboma, hypertelorism, growth deficiency, microcephaly, mental retardation, cardiac septal defects | Congenital diaphragmatic hernia, cardiac anomalies, seizures, airway hypotonia/obstruction | 194190 |
| Amnion rupture sequence ^a | Cleft lip and palate, oblique facial clefts, focal areas of scalp aplasia, constriction bands with terminal limb amputations and syndactylies, occasional anencephaly, encephalocele, and ectopia cordis | Encephalocele, oropharyngeal/airway deformation | 217100 |

^aPotential ICU issues.

• **Fig. 100.1** (A) Infant with Robin sequence and significant micrognathia. (B) U-shaped cleft palate. (C) Infant with Robin sequence and a nasopharyngeal tube in place.

obstruction. The tongue can act as a ball valve, leading to inspiratory obstruction. In addition to glossoptosis, other mechanisms may contribute to airway obstruction in individuals with RS, such as pharyngeal hypotonia and airway inflammation from associated gastroesophageal reflux. The principal physiologic sequelae of RS are the inability to effectively feed and breathe due to airway obstruction. In the immediate neonatal period, patients with RS may have increased inspiratory work of breathing, cyanosis, and apnea. Obstruction is more common in the supine position and can be exacerbated during feeding and in sleep or in any state where there is loss of pharyngeal tone. Chronic obstruction can lead to failure to thrive, carbon dioxide retention, pulmonary hypertension, and eventually right-sided heart failure (cor pulmonale).

Airway obstruction is the main cause of feeding and growth issues in infants with RS. Feeding problems can also be related to abnormal coordination, primary swallowing dysfunction, and pharyngeal hypotonia, and suction mechanics are complicated by the presence of a cleft palate. Increased energy expenditures because of the increased work of breathing may lead to failure to thrive if the infant is not receiving adequate caloric intake. Gastroesophageal reflux is common in infants with RS, as it is in other infants who have increased work of breathing.

Management

First and foremost, the airway must be addressed. Placement of a nasopharyngeal (NP) airway or endotracheal tube may be required in an emergency, and it is important to realize that severe, life-threatening airway obstruction can present in the delivery room. Although uncommon, a prenatal diagnosis of micrognathia allows the involvement of neonatologists and otolaryngologists in the delivery room (Costello et al., 2010).

A number of therapeutic maneuvers can be used to stabilize the upper airway in RS, ranging from positioning to surgery. Placing the baby in the prone or lateral decubitus position will often open up the airway and decrease the degree of obstruction. This may improve airway patency and air exchange, which decreases the work of breathing and may also improve tolerance of oral feeding. When prone positioning fails to stabilize the airway, alternative approaches include the use of an NP airway, noninvasive positive pressure, treatment with tongue–lip adhesion (TLA), and mandibular advancement through distraction osteogenesis. Children with isolated airway obstruction at the base of tongue without other medical comorbidities may be considered for mandibular distraction osteogenesis (MDO) (Paes et al., 2013). The surgery consists of surgical osteotomy and placement of distraction device that slowly increases mandibular length and ramus height and brings the base of the tongue forward, thereby increasing the airway space. This procedure will not achieve respiratory stabilization in patients with concomitant airway anomalies, lung disease, central apnea, or the need for positive pressure ventilation. Tracheotomy may be necessary to provide a safe and secure airway in some infants. Treatment protocols differ across institutions (Bookman et al., 2012), and an example of the initial evaluation and clinical team discussion for the neonate with tongue-based airway obstruction is provided in Box 100.1. While the threshold for intervention and the management options differ substantially, most providers agree that most neonates with RS can be treated nonsurgically.

An NP airway provides a temporary way to bypass the infant's airway obstruction (see Fig. 100.1C). An endotracheal tube can be

modified so that it can be passed through the nares into the hypopharynx above the epiglottis, allowing oxygenation/ventilation by bypassing the obstruction at the base of the tongue (Parhizkar et al., 2011). The NP airway may prevent the need for more invasive procedures and allows the team to address oral skills and feeding (Wagener et al., 2003). In some institutions the infant is discharged home with an NP airway in place (Abel et al., 2012). Infants are monitored with oximetry, and parents are taught NP airway maintenance (suctioning) and replacement. The NP tube is typically in place for 3 to 6 months or less if symptoms resolve or other interventions become necessary. Airway compromise and stability are assessed by physical examination, CO₂ levels, oxygenation, overnight sleep studies, and growth, monitored over time (Evans et al., 2011).

When airway obstruction is localized to the tongue base and positioning has not improved breathing and feeding, a TLA may be a temporizing measure to minimize obstruction while allowing for mandibular growth (Schaefer and Gosain, 2003). In some institutions, TLA has been shown to have a high initial success rate for correction of airway obstruction in a neonate. However, long-term follow-up indicates that many infants require secondary interventions to manage their feeding and airway (Denny et al., 2004).

The infant's clinical status, perceived need for long-term respiratory support, and failure of less invasive interventions will

• BOX 100.1 Evaluation and Decision Making for Neonates With Tongue-Based Airway Obstruction

Initial Evaluation in the Neonatal ICU:

Physical examination (supine vs prone): attention to craniofacial features, respiratory status, cardiac and limb differences
 Evaluation for presence of glossoptosis, stertor, obstructive apnea, and work of breathing
 Capillary blood gas and total CO₂ level
 Oxygen saturation monitoring
 Growth parameters
 Dysmorphology evaluation
 Craniofacial and otolaryngology consultations
 Consider genetics evaluation if there are multiple anomalies or a concerning family history (micrognathia, cleft palate, childhood hearing loss/myopia/joint problems)
 Consider airway endoscopy (guided by airway severity and response to interventions)
 Consider airway imaging (guided by airway severity and response to interventions)

Multidisciplinary Team Treatment Discussions May Address:

Does the patient need escalation in care to treat airway obstruction?
 Have appropriate subspecialty consults and evaluations been obtained? (Varies by institution, but can include specialists with expertise in neonatal intensive care, craniofacial and pediatric care, airway evaluations, airway surgery, jaw surgery, parent/family support)
 Should the patient undergo CT to assess the possibility of craniofacial skeleton and MDO (if so, when and how to proceed safely)
 Has the distal part of the airway been evaluated to look for other levels of airway obstruction?
 Does the patient need a tracheostomy tube, or is he/she a candidate for mandibular distraction?
 What is the family and social context?
 What will the disposition be once airway has been stabilized?

CT, Computed tomography; ICU, intensive care unit; MDO, mandibular distraction osteogenesis.

determine whether more invasive surgery is indicated (Evans et al., 2011; Cielo et al., 2016). For some neonates, mandibular distraction osteogenesis may be an alternative to tracheostomy. Airway endoscopy helps to delineate the level of obstruction, and computed tomography (CT) of the facial skeleton provides optimal understanding of jaw anatomy and tooth bud position before distraction. Recognition of other airway anomalies or issues, such as laryngotracheomalacia, subglottic stenosis, and poor secretion handling, will affect decision making regarding airway management. Children with RS associated with syndromes, skeletal dysplasia, or neurologic conditions may have more than one factor contributing to their airway obstruction such that a tracheostomy may be the best approach to alleviate respiratory compromise. Thus infants with RS who have airway obstruction unresponsive to positional techniques (side or prone) for whom surgical options are being considered (mandibular distraction versus tracheostomy) should have a comprehensive airway evaluation as well as a diagnostic evaluation for an underlying syndrome or associated malformations that might impact respiratory status and response to therapies.

Nutrition can be maintained with a hypercaloric formula and/or fortified breast milk given by side-lying feeding using a cleft feeder, via a nasogastric feeding tube, or via a gastrostomy tube. Oral feeding can and should be introduced when the airway is stable. Oral stimulation is important to prevent oral aversion. As tone improves, the child gains better control of the tongue, and growth ensues, feeding will become less of a problem. Close observation for symptoms of gastroesophageal reflux with proactive pharmacologic treatment can minimize airway inflammation.

Given the association with cognitive and motor delay, close monitoring of development and referral to early intervention services, such as a Birth to Three program, are recommended.

Stickler Syndrome

The most common syndrome associated with RS is Stickler syndrome. Between 20% and 30% of individuals with RS will have Stickler syndrome (Izumi et al., 2012). Stickler syndrome is most commonly an autosomal dominant (with variable expressivity) connective tissue disorder with ophthalmic, orofacial, auditory, and articular manifestations and has been divided into six types (Stickler syndrome types I and II have ocular findings, type III is nonocular, and types IV to VI are recessive conditions) (Robin et al., 2017).

Stickler syndrome is characterized by cleft palate, hearing loss, arthropathy, joint hypermobility, reduced height, and eye abnormalities, including myopia, cataracts, glaucoma, and retinal detachment. The myopia of Stickler syndrome is usually congenital, nonprogressive, and of high degree. Facial features include flat midface with depressed nasal bridge, short nose, anteverted nares, and micrognathia, telecanthus, and epicanthal folds with a concave facial profile (Fig. 100.2). Sensorineural hearing loss is more common in type II Stickler syndrome.

The diagnosis of Stickler syndrome should be considered in any neonate with RS or a cleft palate, especially when associated with myopia or hearing loss. Spondyloepiphyseal dysplasia is not usually apparent in the newborn period. Mutations affecting one of six genes (*COL2A1*, *COL9A1*, *COL9A2*, *COL9A3*, *COL11A1*, and *COL11A2*) have been associated with Stickler syndrome, and clinical molecular testing by sequence analysis is available for all types. More than 90% of individuals with Stickler

• **Fig. 100.2** Infant with Stickler syndrome, showing a flat face, depressed nasal bridge, and epicanthal folds. This infant also has Robin sequence and required tracheostomy.

syndrome are found to have a mutation in either *COL2A1* (Stickler syndrome type I, Online Mendelian Inheritance in Man [OMIM] 108300) or *COL11A1* (Stickler syndrome type II, OMIM 604841) (Robin et al., 2017). The diagnosis should also be considered in any newborn with a family history of RS or Stickler syndrome features.

In addition to appropriate management of feeding, breathing, and growth (as described earlier in RS), management of Stickler syndrome includes active detection of the ocular features of the syndrome, such as myopia. This is because the associated risk of retinal detachment and blindness are preventable. An initial ophthalmology evaluation is recommended for all children with RS aged between 6 and 12 months or at the time of a definitive molecular diagnosis of Stickler syndrome and then routine surveillance thereafter.

Orofacial Clefting

Epidemiology

Orofacial clefts of the primary and secondary palate are among the most common congenital anomalies. Classified as either cleft lip with or without CP (CL±P) or CP only (CPO), these two phenotypes are thought to be distinct in origin. One case of orofacial cleft occurs in approximately every 500 to 550 births, and on an average day in the United States, 20 infants are born with an orofacial cleft (Tolarova and Cervenka, 1998). Cleft lip and palate is the most common type of orofacial clefting, followed by cleft lip, then CPO, and less prevalent are atypical clefts (macrostomia or lateral cleft, oblique and midline clefts). Unilateral CL±P is more common than bilateral involvement (Genisca et al., 2009). A bifid uvula can be a normal variant, found in 2% to 4% of births, but can also be a sign of an associated submucous cleft palate, which can have the same functional impact as an overt CP (Hennekam et al., 2010a, Ch 21).

The causes of most orofacial clefts are unknown and are nonsyndromic (isolated) in 70%–75% of infants with CL±P and approximately 50% of those with CPO (Tolarova and Cervenka, 1998; Leslie and Marazita, 2013). Neonates with orofacial clefting

who are born prematurely or have low birth weight may have a higher incidence of associated congenital malformations (Milerad et al., 1997). Racial and ethnic variation in the prevalence of clefts has been described, with the highest prevalence of CL±P found in Native Americans, followed by whites and Hispanics, and the lowest overall prevalence of CL±P demonstrated in African Americans (Croen et al., 1998). The cause of nonsyndromic clefts is complex and multifactorial, likely resulting from interaction between environmental and genetic factors. Known environmental risk factors include maternal tobacco smoking, alcohol use, anticonvulsant treatment, and nutritional status. Recognition of contributing genetic factors such as a mutation in *IRF6* resulting in Van der Woude syndrome is increasing, and the impact of folate supplementation as an environmental modulator is under investigation (Mossey et al., 2009; Wehby and Murray, 2010). Although many candidate genes have been described, there is no routinely recommended genetic testing for a child with isolated CL±P in the absence of a family history. Recurrence risk information for the parents of a child with CL±P or for the affected individual is dependent either on the specific syndrome/genetic diagnosis or on empiric risks for those with nonsyndromic clefting. For a family with just one child affected with CL±P, the recurrence risk is 2%–5% for a subsequent child, increasing to 10%–15% if there are other family members with clefts. The recurrence risk is slightly less if the child has CPO (Harper, 2011).

Anatomy

The embryologic development of the primary palate begins very early in gestation, and the upper lip and primary palate have usually fused by the seventh week of gestation. A failure of fusion of the medial and lateral nasal processes with the maxillary process produces CL±P. Clefts can affect the primary palate (lip, alveolus, or anterior portion of the hard palate that extends to the incisive

foramen) and secondary palate (posterior hard palate and soft palate). Clefts of the primary and secondary palate can be unilateral or bilateral and complete or incomplete. A complete cleft of the primary palate leaves no residual tissue between the alar base and the lip, whereas an incomplete cleft does not extend through the floor of the nose (Fig. 100.3A–C, F).

Phenotype

The cleft of the primary and secondary palate will affect facial shape and growth (see Fig. 100.3A–C). Children with CP are at increased risk of eustachian tube dysfunction, recurrent otitis media, and acquired hearing loss, as well as speech issues later in childhood. Associated dental findings include hypodontia and, less commonly, natal teeth. Feeding difficulties, nasal regurgitation of feeds, and difficulty gaining weight may occur in infants with a CP (submucous and overt clefts of the palate).

Lateral facial clefting or macrostomia is pathogenically distinct from isolated cleft lip/palate and is often associated with syndromes, including craniofacial microsomia (CFM) and Treacher Collins syndrome (TCS). Amniotic rupture sequence can be associated with oblique facial clefts and may be associated with underlying central nervous system (CNS) malformations and transverse limb anomalies.

A true median cleft of the upper lip is the rarest type of facial clefting (see Fig. 100.3D). Midline clefting can be associated with other congenital defects as can be seen in orofaciogigital syndrome and frontonasal dysplasia (FND), and CNS malformations are common in children with midline clefts. Some midline clefts are not true clefts but represent hypoplasia or agenesis of the primary palate or premaxillary agenesis, which can be associated with holoprosencephaly (HPE) sequence (see Fig. 100.3E). Infants with HPE often have a depressed nasal tip and a short columella and appear hypoteloric (compared with FND or frontonasal encephalocele, where midline clefting may

• **Fig. 100.3** (A) Infant with a unilateral incomplete cleft lip. (B, C) Infant with bilateral complete cleft lip and palate. (D) Infant with midline cleft and hypertelorism. He also has a frontonasal encephalocele. (E) Infant with premaxillary agenesis and holoprosencephaly. (F) Infant with Van der Woude syndrome with unilateral complete cleft lip and a lip pit (arrow).

be present, but the infant has a broad nasal tip and/or columella and hypertelorism).

Orofacial clefting is rarely associated with clefting of the airway structures, such as cleft larynx or extension of clefting into the trachea. Opitz G/BBB syndrome is a multiple congenital anomaly syndrome characterized by facial anomalies (100% will be hypertelorism and 50% will have CL±P), genitourinary abnormalities (90% will have hypospadias), and laryngotracheoesophageal (LTE) defects (present in 70%) (Meroni, 2011). Autosomal dominant (OMIM 145410) and X-linked recessive (OMIM 300000) forms of Opitz G/BBB syndrome are recognized. Pallister–Hall syndrome (PHS; OMIM 146510) is characterized by a constellation of findings that include hypothalamic hamartoma (resulting in seizures and pituitary dysfunction), polydactyly, airway clefting, and other anomalies (genitourinary, renal, pulmonary, and imperforate anus). Bifid epiglottis is the most common airway manifestation in PHS, although LTE clefts have been reported. LTE defects may range from LTE dysmotility in mild forms to laryngeal or tracheoesophageal clefts in more severe forms.

ICU Concerns

Most infants with CL±P do not require ICU care. Thus an infant with an apparently isolated cleft who develops significant respiratory or electrolyte abnormalities requiring ICU care should be considered syndromic until proven otherwise. In these infants a genetics consultation should be considered.

The newborn with a midline cleft or premaxillary agenesis is at risk of serious underlying CNS anomalies, including HPE. In the presence of HPE, detection of associated medical issues is important. Endocrine abnormalities can arise because the midline malformation affects the development of the hypothalamus and the pituitary gland. Clinical manifestations can include growth hormone deficiency, adrenal hypoplasia, hypogonadism, diabetes insipidus, and thyroid deficiency. Neurologic manifestations that warrant close attention include seizures, hypotonia, spasticity, autonomic dysfunction, and developmental delays.

With an LTE cleft, there is longitudinal communication between the airway and the esophagus, allowing tracheal aspiration of oral contents, including saliva and feeds. Clefting of the larynx may result in stridor, a hoarse cry, respiratory distress, swallowing dysfunction, feeding difficulties, regurgitation, and aspiration, hypoxia, recurrent pneumonias, and eventually severe respiratory compromise if unrecognized. An infant boy with hypertelorism, hypospadias, orofacial clefting, and symptoms of airway obstruction or aspiration should be evaluated for Opitz syndrome. Infants with PHS may also have respiratory distress due to airway clefting, as well as other potentially life-threatening clinical manifestations such as seizures and severe panhypopituitarism. Genetic evaluation and consideration of molecular testing for Opitz syndrome and PHS can be coordinated through a geneticist.

Management

The specifics of management of orofacial clefting are center specific. Because of the potential impact of the orofacial cleft on breathing, eating, hearing, speech, facial growth, and dental health, it is recommended that infants and children with clefts be referred to a multidisciplinary care team for long-term management. In remote areas, the nearest cleft team may be found through the American Cleft Palate–Craniofacial Association (ACPA) team listings (American Cleft Palate–Craniofacial Association, 2017). Overviews of

recommended team care for patients with cleft lip/palate can be accessed electronically (American Cleft Palate–Craniofacial Association, 2009; The Center for Children with Special Needs, 2010).

On the initial assessment, the provider should assess the cleft and examine the infant for dysmorphic features and other anomalies. Hearing should be evaluated by evoked otoacoustic emissions or by brainstem auditory evoked response if the newborn does not pass the initial hearing screen. A neonate with a complete cleft lip should be evaluated by a craniofacial or cleft team in the first 2 weeks of life, and some centers offer taping or presurgical molding (nasal alveolar molding) that can be initiated in this period.

Many mothers will be able to breastfeed an infant born with an isolated cleft lip. Breastfeeding a baby with CP (with or without cleft lip) will prove extremely challenging because the open palate will not generate the negative pressure needed for sucking. Thus infants with CP with or without cleft lip should be offered expressed breast milk or infant formula with use of a specialized cleft feeder. A variety of cleft nipples/bottles have been devised to allow oral feeding, including the CP nurser (squeeze bottle), Haberman feeder, Pigeon bottle, and Dr. Brown bottle with a cleft valve (<http://www.cleftline.org/who-we-are/what-we-do/feeding-your-baby/>). Infants with CP tend to swallow more air during feedings. The child should feed in an upright position, as gravity will help prevent nasal regurgitation. If the child is still having difficulty feeding, a feeding specialist should be consulted. Adequate weight gain is important for overall health and readiness for the surgical procedures that occur in the first year of life. Newborns with clefts are considered nutritionally high risk, and a dietitian should be consulted to help determine caloric needs and to closely monitor growth.

In general, surgical closure of the lip and nasal deformity is done within the first 6 months of life. Palatoplasty typically occurs between 9 and 12 months of age to optimize speech and language development.

If there are concerns about airway clefting or anomalies of the larynx or trachea, a chest X-ray should be obtained and the airway evaluated, in addition to appropriate evaluation of associated anomalies. Microlaryngoscopy with the patient under general anesthesia remains the gold standard in the diagnosis of a laryngeal cleft (Johnston et al., 2014). Given the risk of gastrointestinal manifestations such as gastroesophageal reflux, dysmotility, and aspiration, antireflux precautions should be initiated in infants with suspected or confirmed LTE defects. Early diagnosis and proper repair of the laryngeal cleft are essential to prevent injury to the lungs. Significant LTE defects will need to be managed surgically, and tracheostomy may be necessary initially to ensure airway stability and safety.

In the presence of a midline cleft, it is important to evaluate the patient for underlying CNS malformations such as HPE. In any child with a midline cleft or facial features consistent with premaxillary agenesis/hypoplasia, CNS imaging (CT or MRI) is recommended. Consultation with a geneticist or genetic counselor may provide insight into the genetics, molecular testing options, and recurrence risk of HPE. Treatment of HPE is supportive and based on symptoms. The outcome depends on the severity of HPE and the associated medical and neurologic manifestations.

Syndromes Associated With Cleft Lip and/or Palate

It is estimated that there are more than 400 syndromes associated with orofacial clefts (Hennekam et al., 2010a). The frequency

with which associated malformations are encountered with CL±P is approximately 25% (Genisca et al., 2009). In approaching diagnosis of a syndrome, one should categorize the type of cleft (CL±P, U-shaped or V-shaped cleft palate, or more atypical orofacial cleft) and look for any other malformations. Table 100.1 describes the syndromes most commonly associated with clefting and the key features, potential ICU issues, and OMIM database classification. The OMIM database at the National Library of Medicine is a comprehensive collection of more than 15,000 human genes and genetic phenotypes. A referral to a clinical geneticist is recommended when an underlying diagnosis is suspected but not established.

22q11.2 Deletion Syndrome

Epidemiology and Genetics

22q11.2 deletion syndrome is a genetic condition with an estimated prevalence of 1 in 1000 births in which affected individuals are missing a region (typically 3 Mb, encompassing approximately 40 genes) on one copy of chromosome 22 (Carlson et al., 1997; McDonald-McGinn et al., 2015). Before the availability of genetic testing for this condition, individuals with clinical features of 22q11.2DS were classified under a range of other clinical syndromes, such as DiGeorge syndrome, velocardiofacial syndrome, and Shprintzen syndrome. Subsequently, a subset of children with overlapping features in these conditions (such as congenital heart disease and cleft palate) were also noted to share a deletion on chromosome arm 22q. It was later discovered that the most children in whom either DiGeorge syndrome or velocardiofacial syndrome has been clinically diagnosed share the deletion on one copy of chromosome 22. It has been estimated that more than 90% of individuals with “classic” features of 22q11.2DS have a detectable 22q deletion (McDonald-McGinn et al., 2013). 22q11.2DS is associated with more than 180 clinical features, and phenotypic variation is a hallmark of this genetic condition (McDonald-McGinn et al., 2015).

Phenotype

In neonates, 22q11.2DS presents in various ways. In some infants this condition is diagnosed prenatally. Testing may occur as part of the evaluation for fetuses with congenital heart disease or because of a parental history of 22q11.2DS. The clinical indications for genetic testing for this condition in neonates frequently include congenital heart malformations (particularly conotruncal anomalies), seizures secondary to hypocalcemia, dysphagia, cleft palate, and/or respiratory distress secondary to upper airway obstruction. 22q11.2DS commonly has multiorgan system involvement, including cardiac and palatal abnormalities, immune differences, endocrine and gastrointestinal problems, and later-onset conditions across the life span, including variable cognitive deficits and

psychiatric illness. In this section, we focus on the evaluation of infants with craniofacial characteristics suggestive of 22q11.2DS.

Several craniofacial features have been observed in individuals with 22q11.2DS; however, many of these are subtle and may not be apparent in the newborn period. Common features identified on the newborn physical examination include cleft palate, small, overfolded helices, and tapered fingers. Other clues to the diagnosis include dysphagia and/or nasal regurgitation (even in the absence of an overt cleft palate), congenital heart disease (most commonly conotruncal anomalies), and hypocalcemia.

An estimated 8% of infants with CP have 22q11.2DS (Hennekam et al., 2010b). For this reason, recommendations differ regarding routine testing of infants with isolated cleft palate. Most agree, however, that molecular testing is indicated for children with a CP in combination with any of the other features that can be observed in 22q11.2DS. The accurate identification of 22q11.2-associated disorders impacts medical surveillance, management, and counseling. Clinical testing with chromosomal microarray or multiplex ligation-dependent probe amplification will capture deletions, duplications, and smaller changes including those that would not be detected with fluorescence in situ hybridization for 22q deletion.

Evaluation and Management

Families of infants, for whom there is a high clinical suspicion and those testing positive for this deletion, should receive genetic counseling. Individuals with 22q11.2DS should undergo studies to identify associated health concerns. These screening evaluations include a total lymphocyte count (low absolute lymphocyte count necessitates evaluation of T-cell and B-cell subsets and referral to an immunologist), hematocrit, platelet count, and total and ionized calcium levels to screen the infant for hypocalcemia. Additional studies include echocardiogram to evaluate the infant for congenital heart malformations and renal ultrasonography. Newborns should have a palatal examination to evaluate them for overt or submucous clefting, as well as a diagnostic hearing test. Infants with evidence of dysphagia (even in the absence of a palatal cleft) benefit from an evaluation by a feeding specialist to determine if a swallow study is needed or if a cleft bottle would be helpful. Additional recommendations for screening evaluations and management have been outlined by McDonald-McGinn et al. (2015).

Craniosynostosis

Definitions/Epidemiology

Craniosynostosis refers to the premature fusion of one or more cranial sutures (metopic, sagittal, right or left coronal, or right or left lambdoid) that normally separate the bony plates of the cranium. The birth prevalence of all craniosynostoses is estimated to be 1 in 2500 live births (Boulet et al., 2008).

Typically, patent sutures allow the calvaria to expand as the brain grows, producing the normal head shape and size. If one or more sutures fuse prematurely, there is restricted growth perpendicular to the fused sutures and compensatory growth in the patent sutures, producing an abnormal head shape. Craniosynostosis is a heterogeneous disorder with significant health consequences that range from an abnormal head shape and increased intracranial pressure (ICP) to secondary visual and intellectual impairments. Known causes of primary craniosynostosis include monogenic and chromosomal abnormalities as well as environmental factors. Nonsyndromic single suture craniosynostosis accounts for 85% of patients. Syndromic

TABLE 100.2 Craniosynostosis Syndromes and Potential Airway Compromise

| Syndrome | Key Features | Tracheal Abnormalities | Midface Hypoplasia | OMIM |
|---|--|--|--|--------|
| Apert syndrome ^a | Craniosynostosis (coronal > lambdoid > sagittal), acrobrachycephaly (steep, wide forehead and flat occiput), proptosis, hypertelorism, exotropia, trapezoid-shaped mouth, prognathism, invariable symmetric syndactyly of hands and feet, variable elbow fusion, cognitive impairment, narrow palate with lateral palatal swellings, widely patent sagittal suture connecting anterior and posterior fontanels | Tracheoesophageal fistula, tracheal cartilaginous sleeve less common | Significant maxillary hypoplasia, obstructive sleep apnea syndrome | 101200 |
| Crouzon syndrome ^a | Craniosynostosis (coronal > lambdoid > sagittal), brachycephaly, prognathism, exophthalmos, papilledema, hypermetropia, divergent strabismus, atresia of auditory canals, Chiari type 1 malformation and hydrocephalus | Solid cartilaginous trachea or tracheal cartilaginous sleeve | Significant maxillary hypoplasia, obstructive sleep apnea syndrome | 123500 |
| Pfeiffer syndrome types I, II, and III ^a | Craniosynostosis (coronal > sagittal > lambdoid), brachycephaly, hypertelorism, proptosis, broad first digits with radial deviation, variable syndactyly and elbow fusion, cloverleaf skull | Solid cartilaginous trachea or tracheal cartilaginous sleeve | Significant maxillary hypoplasia, obstructive sleep apnea syndrome | 101600 |
| Muenke syndrome | Unilateral or bilateral coronal craniosynostosis, brachydactyly, downslanting palpebral fissures, thimble-like middle phalanges, coned epiphysis, carpal and tarsal fusions, sensorineural hearing loss, Klippel–Feil anomaly | | Mild maxillary hypoplasia, no airway compromise anticipated | 602849 |
| Saethre–Chotzen syndrome ^a | Unilateral or bilateral coronal craniosynostosis, acrocephaly, brachycephaly, low frontal hairline, hypertelorism, facial asymmetry, ptosis, characteristic ear (small pinna with a prominent crus), fifth finger clinodactyly, partial 2–3 syndactyly of the fingers, duplicated halluces | | Maxillary hypoplasia | 101400 |
| Carpenter syndrome | Craniosynostosis (coronal > lambdoid > sagittal), hypertelorism, proptosis, brachycephaly, brachydactyly, preaxial polysyndactyly, mental retardation | | Maxillary hypoplasia | 201000 |
| Jackson–Weiss syndrome | Craniosynostosis (coronal), acrocephaly, hypertelorism, proptosis, midface hypoplasia, radiographic abnormalities of the foot including fusion of the tarsal and metatarsal bones, 2–3 syndactyly, broad short first metatarsals and broad proximal phalanges | | Maxillary hypoplasia | 123150 |

^aSignificant risk of airway morbidity.
OMIM, Online mendelian inheritance in man.

cranosynostosis may involve single or multiple fused sutures, additional anomalies (such as limb, cardiac, CNS, and tracheal malformations), and developmental delay. Multiple suture involvement is usually considered hereditary even when it does not fit a classic pattern of anomalies. Advances in molecular genetics and next-generation sequencing have led to the identification of causative mutations and genetic pathways in these relatively common congenital anomalies (Twigg and Wilkie, 2015a, 2015b). The genetic cause of craniosynostosis in humans is only partially understood. However, for most syndromic forms, identification of the primary genetic cause and contributing factors is possible with use of clinically available genetic tests (Agochukwu et al., 2012).

Single Suture Synostosis

Sagittal synostosis is the most common single suture synostosis (50%–60%), with a prevalence of 1.5 per 10,000 live births (Boulet et al., 2008). Known risk factors include male sex, intrauterine head constraint, twin gestation, thyroid hormone dysregulation,

and maternal smoking. Although uncommon, the most frequently encountered associated anomalies include congenital heart defects and genitourinary tract malformations. Syndromes with synostosis involving only the sagittal suture are rare. Premature union of the sagittal suture hinders normal calvarial expansion, leading to scaphocephaly, an elongated, narrow calvarium, decreased bitemporal diameter, and frontal and occipital bossing (Fig. 100.4). Premature fusion of the suture before birth leads to abnormal head shape in the newborn period. A breech-positioned neonate can have scaphocephaly or dolichocephaly that may mimic sagittal synostosis. However, in sagittal synostosis, frontal bossing and biparietal narrowing progress, whereas the head shape in a breech-positioned infant will normalize in the first month of life. There is a concern that children with single suture synostosis are at risk of elevations in ICP, local brain injury, and later developmental delays. Although school-age children born with single suture craniosynostosis have been found to have evidence of mild developmental delays, the pathogenesis and direct relationship to synostosis have not been determined (Speltz et al., 2015).

• **Fig. 100.4** Head shapes in single suture synostosis. From left to right: normal head shape, sagittal synostosis, coronal synostosis, and metopic synostosis.

Coronal synostosis is the second most common single suture synostosis (20%–30%), with a prevalence of 0.7 per 10,000 live births (Boulet et al., 2008). The skull is notable for a flat supraorbital rim and orbit that appears higher on the affected side, with a frontal bulge on the contralateral side (see Fig. 100.4). The nose often appears to twist away from the coronal fusion. Genetic syndromes are more frequently seen in individuals with coronal synostosis, including Saethre–Chotzen syndrome, Muenke syndrome, and craniofrontonasal dysplasia. All families of children with coronal synostosis should be offered genetic consultation and/or genetic testing to include *FGFR2*, *FGFR3*, *TWIST1*, *TCF12*, and *EFNB1* on the basis of clinical examination.

Metopic synostosis (15%–20% of single suture craniosynostosis) has a prevalence of 0.8 per 10,000 live births (Boulet et al., 2008), although recent reports suggest that metopic synostosis may be as common as coronal synostosis (Lee et al., 2012). Risk factors include male sex, twin gestation, and in utero exposure to valproate. Syndromes, associated anomalies, and chromosomal abnormalities occur in approximately one-quarter of individuals with metopic synostosis (Lajeunie et al., 1998; Azimi et al., 2003). Premature fusion of the metopic suture results in a triangular head shape, or trigonocephaly, which features a midline forehead ridge, fronto-temporal narrowing, pterion constriction, hypotelorism, and an increased biparietal diameter (see Fig. 100.4). Isolated metopic ridging is common in infancy, does not distort forehead shape, and is not associated with metopic synostosis.

Lambdoid synostosis (3% of single suture craniosynostosis) is the least common form of single suture synostosis. It is characterized by flattening of the ipsilateral occiput, posterior–inferior displacement of the ear, bulge of the mastoid process on the fused side, and a skull base tilted downward on the affected side.

Multiple Suture Synostosis

Multiple suture (or *multisuture*) *synostosis* describes patients who have two or more fused sutures. Although children with multisuture synostosis are more likely to have a known syndromic form of

craniosynostosis such as Apert syndrome, Crouzon syndrome, or Muenke syndrome, some have chromosome aberrations or patterns of craniosynostosis with associated anomalies not previously described. With 20 known hereditary forms of craniosynostosis, genetic consultation and counseling are of critical importance in the management of these conditions (Twigg and Wilkie, 2015a, 2015b). Here we briefly discuss select major syndromes with craniosynostosis that may have medical issues in the newborn period. See Table 100.2 for a description of key phenotypic features and potential airway compromise.

Apert syndrome (OMIM 101200) was initially described as acrocephaly with four-limb syndactyly. It accounts for 4.5% of all craniosynostosis (Hennekam et al., 2010c; Fig. 100.5). It is inherited as an autosomal dominant trait and is associated with advanced paternal age. Neurocognitive outcomes differ, but a moderate to severe degree of cognitive impairment is most common. Four mutations in *FGFR2* causing Apert syndrome have been identified.

Crouzon syndrome (OMIM 123500) is an autosomal dominant condition that demonstrates wide phenotypic variability. Shallow orbits with proptosis are an important diagnostic finding, although this feature may be subtler in the newborn (Fig. 100.6). Significant abnormalities involving the CNS include the frequent presence of a Chiari type 1 malformation, with progressive hydrocephalus resulting in intracranial hypertension. Compared with Apert syndrome, Crouzon syndrome is associated with more extensive suture involvement, smaller cranial volume, and more severe intracranial constraint; however, cognitive development is usually normal. Like Apert syndrome, Crouzon syndrome is caused by mutations in *FGFR2*. A less common form of Crouzon syndrome with acanthosis nigricans skin findings developing in the first 2 years of life is caused by a transmembrane mutation in *FGFR3* (OMIM 612247).

Pfeiffer syndrome (OMIM 101600) is a hereditary craniosynostosis that shares significant overlap, both phenotypically and genetically, with Crouzon syndrome. It is an autosomal dominant inherited disorder with craniosynostosis accompanied by proptosis, broad and deviated thumbs and big toes, and

• **Fig. 100.5** (A) Infant with Apert syndrome, a high and full forehead, proptosis and exotropia, midface hypoplasia, and a trapezoid-shaped mouth. (B, C) Hands and feet in Apert syndrome. Note the syndactyly symmetrically affecting hands and feet. All five digits may be webbed, or a single toe, finger, or thumb may be free.

• **Fig. 100.6** (A) Infant with Crouzon syndrome with brachycephaly. (B) Proptosis is seen in the lateral view.

partial syndactyly of the hands and feet (Fig. 100.7). Mutations in *FGFR1* and *FGFR2* cause Pfeiffer syndrome. Type 1 (i.e., classic) Pfeiffer syndrome involves mild manifestations including brachycephaly, midface hypoplasia, and digital malformations. Type 2 consists of cloverleaf skull, extreme proptosis, digital malformations, elbow ankylosis, developmental delay, and neurologic complications. Type 3 is similar to type 2 but without a cloverleaf skull.

Muenke syndrome (OMIM 602849) is an autosomal dominant syndrome caused by a single P250R mutation in the *FGFR3* gene. Like Apert syndrome, Muenke syndrome is associated with advanced paternal age. Individuals with Muenke syndrome may have coronal craniosynostosis (unilateral or bilateral) or macrocephaly and variable

degrees of proptosis, without significant midface hypoplasia (Fig. 100.8).

Saethre–Chotzen syndrome (OMIM 101400) is caused by a mutation in the *TWIST1* gene on chromosome 7. The inheritance is autosomal dominant, and many children with Saethre–Chotzen syndrome will have an affected parent. In addition to craniosynostosis, affected individuals commonly have a low frontal hairline, ptosis, 2–3 syndactyly of the fingers, cervical spine anomalies, and duplicated halluces. Although learning difficulties may be noted, cognitive impairment is not typical of Saethre–Chotzen syndrome caused by intragenic mutations. Children with deletions rather than point mutations often demonstrate significant developmental delays.

• **Fig. 100.7** (A, B) Infant with Pfeiffer syndrome, brachycephaly, a high forehead, midface hypoplasia, proptosis, and ocular hypertelorism. (C) An older child with Pfeiffer syndrome and the typical broad thumbs with radial deviation.

• **Fig. 100.8** (A, B) Infant with Muenke syndrome, acrobrachycephaly due to bicoronal synostosis, and absence of proptosis. (C) Sibling of the infant in (A, B) also with Muenke syndrome; note the downslanting palpebral fissures.

Cloverleaf skull can result from any form of multisuture craniosynostosis. The skull forms a trilobular appearance, as the cerebrum bulges through the sagittal and squamosal sutures, because of craniosynostosis affecting the coronal, metopic, and lambdoid sutures. Cloverleaf skull can be isolated or more commonly associated with a syndrome, and it is estimated that up to 20% of cases represent Pfeiffer syndrome.

ICU Concerns

The most significant concerns for the newborn with craniosynostosis are airway compromise (specifically, upper airway obstruction) and intracranial hypertension.

Midface hypoplasia and tracheal anomalies that may be present in syndromic craniosynostosis can lead to significant airway compromise (see [Table 100.2](#)). With midface hypoplasia, there is decreased NP/oropharyngeal space because of a small maxilla, narrowing at the level of the posterior choanae and posterior displacement of bony and soft tissue structures, leading to breathing problems, obstructive sleep apnea, asphyxia, and even death ([Fig. 100.9](#)). Obstructive sleep apnea is common in Apert, Pfeiffer, and Crouzon syndromes.

Cartilaginous tracheal abnormalities can be present in multisuture craniosynostosis syndromes. Vertically fused tracheal cartilage (also referred to as tracheal cartilaginous sleeve, solid cartilaginous trachea, and stovepipe trachea) in Crouzon and Pfeiffer syndromes may produce a rigid trachea resulting in upper airway stenosis, inability to clear secretions, and increased risk of injury because of decreased distensibility. Characteristic tracheal cartilaginous rings are fused to form a continuous sleeve of cartilage, which may extend from

below the subglottis to the carina or bronchus; rarely, the cartilaginous sleeve can begin more proximally, at the level of the cricoid cartilage. Infants with congenital tracheal anomalies may have fixed stridor, apnea, cyanosis, or increased work of breathing because of multilevel airway obstruction.

Neurologic abnormalities such as hydrocephalus and increased ICP may arise, especially in multisuture craniosynostosis. Increased ICP due to constraint of the growing brain within a restricted calvarium is usually of low grade and chronic, causing symptomatic intracranial hypertension when brain growth is rapid during the first 2 years of life. ICP issues in the neonate are not usually life threatening, given the open fontanel and compensatory splaying of normal sutures or erosion of the calvarium, but brain injury and cognitive impairment may result if skull-expanding surgery is not performed.

Hydrocephalus, which is more common in Crouzon and Pfeiffer syndromes compared with other multisuture synostosis syndromes, can occur as a result of obstruction of cerebrospinal fluid at the basal cistern, aqueductal stenosis, or impeded venous flow or when there is an associated Chiari malformation. Hydrocephalus is extremely common in cloverleaf skull. Individuals with multisuture craniosynostosis (particularly Apert syndrome) more commonly have nonprogressive distortion ventriculomegaly or compensated hydrocephalus, which does not require shunting ([Collmann et al., 2005](#)). Abnormalities of the corpus callosum and septum pellucidum have been described in Apert syndrome, and neuroimaging and genetic advances will illustrate links between brain architecture, phenotype, and genotype ([Fernandes et al., 2016](#)). Seizures presenting in multisuture craniosynostosis syndromes are usually due to encephalopathy rather than increased ICP. Epilepsy is more common

• **Fig. 100.9** (A, B) Three-dimensional reconstruction of a child with Apert syndrome with significant midface hypoplasia, leading to upper airway obstruction. Also notable is acrobrachycephaly due to bicoronal synostosis and the typical pattern of sagittal suture patency. (C) Computed tomography (CT) scan axial slice at the level of the skull base in a newborn with Apert syndrome. The arrow pointing to the airway illustrates significant airway obstruction. (D) CT scan of a newborn illustrating a normal airway (arrow).

with increasing number of sutures involved, and seizures occur in approximately 10% of individuals with Crouzon syndrome (Cohen, 2000).

Conductive and mixed hearing loss, most commonly due to middle ear disease, ossicular abnormalities, and external auditory canal stenosis or atresia, can be present in syndromic craniosynostosis. Profound sensorineural hearing loss has been described in Saethre–Chotzen syndrome (Lee et al., 2002).

Evaluation

The evaluation of the patient with craniosynostosis includes recognizing and confirming the type of suture fusion, clinical syndrome identification, evaluation for associated anomalies, and preparedness for surgical repair. A craniofacial team made up of the appropriate specialties allows proper planning and coordination so that the patient may receive the best possible care (McCarthy et al., 2012).

The family and prenatal history, including documentation of affected family members, teratogen exposure, maternal thyroid

disease, and in utero constraint (oligohydramnios, twins, fetal movement), and the birth history should be ascertained, specifically looking for risk factors.

A detailed physical examination should be performed as part of the initial evaluation, looking for any other anomalies, with specific attention to cleft palate, limb defects, heart defects, and ear anomalies. The assessment of cranial and face shape, mobility of the sutures, presence of sutural ridging, skull base symmetry, and ear position is important. Facial appearance, with particular attention to the degree of maxillary hypoplasia, is important in determining the risk of airway compromise due to midface hypoplasia. If concerning airway symptoms are present, such as snoring, stridor, or apnea, consultation with a sleep specialist and polysomnography may help to quantify the presence and severity of obstructive sleep apnea. Consultation with an otolaryngologist and airway endoscopy may help identify the types and degree of airway narrowing (Wenger et al., 2017). Particular attention to the presence of tracheal malformations, such as vertically fused tracheal cartilage, is crucial in some craniosynostosis syndromes.

With the increased awareness of this condition, the diagnosis of these tracheal malformations is increasingly made on direct laryngoscopy/bronchoscopy or with MRI.

Neurologic assessment includes ascertaining the history, brain imaging, an audiologic evaluation (early screening for hearing loss in conjunction with regular otologic examinations), ophthalmologic evaluation, and ongoing developmental assessments. In multisuture craniosynostosis, it is important to monitor the patient for any signs or symptoms of increased ICP. Evaluation of the patient for hydrocephalus should be a part of the initial assessment of all children with multisuture craniosynostosis. CT with three-dimensional reconstruction will ultimately confirm the diagnosis of craniosynostosis, delineate the degree of suture involvement, and help with preoperative planning. MRI may be helpful in defining any associated CNS anomalies. Ophthalmology consultation is valuable in management of proptosis, strabismus, or nystagmus and in determining the presence of papilledema or optic atrophy.

In addition to the foregoing general recommendations, syndrome-specific recommendations are outlined as follows. In Apert syndrome a cardiac and genitourinary evaluation is recommended. If proptosis is present, as can occur in Apert, Crouzon, and Pfeiffer syndromes, ocular lubricants may be helpful in prevention of exposure keratopathy. In Apert, Crouzon, Pfeiffer, and Saethre-Chotzen syndromes, associated vertebral anomalies, especially fusions, may be present, detected on spine radiographs, and more accurately visualized with CT imaging. If any limb abnormalities are seen, as in Apert, Jackson-Weiss, Pfeiffer, and Saethre-Chotzen syndromes, radiographs with orthopedic consultation should be obtained.

All individuals with single suture synostosis and developmental delay or associated birth defects should be evaluated by a geneticist to determine association with a clinical syndrome and the role of genetic testing. The families of children with multisuture synostosis caused by known classic craniosynostosis syndromes should be offered appropriate genetic testing and genetic counseling. The remaining children with multisuture synostosis in the absence of a known syndromic form should be offered genetic consultation and possible molecular genetic testing.

Management

Although the specific timing of the surgical treatment may differ between teams, it is generally accepted that individuals with synostosis should undergo cranial surgery in the first year of life. Cranioplasty involves release of fused sutures and repositioning and reconstruction of the calvaria, so as to prevent increased ICP and progressive abnormal craniofacial development. Several techniques, including endoscopic strip craniectomy, calvaria distraction, and traditional cranioplasty, are currently used.

Early recognition of tracheal malformations can be lifesaving (Letsburapa et al., 2010). Awareness of potential airway compromise and proactive airway management are crucial in many craniosynostosis syndromes. Temporizing measures to bypass airway obstruction include placement of nasal stents, endotracheal intubation, and ultimately tracheostomy. Specific airway management in syndromic craniosynostosis will depend on the level and severity of obstruction. Serious caution must be exercised in the placement and care of tracheostomies in patients with tracheal cartilaginous sleeve malformation because of abnormal tissue healing and granulation tissue formation. Midfacial surgery may be necessary in some children who have problems with airway obstruction, swallowing,

feeding, and dental malocclusion. This is usually performed later in childhood.

For all individuals with craniosynostosis, we recommend involvement of a craniofacial team, including members specializing in pediatrics, neurosurgery, ophthalmology, oral surgery, orthodontics, otolaryngology, nursing, nutrition, plastic surgery, and social work.

Disorders of the First and Second Branchial Arches

Craniofacial Microsomia

Epidemiology and Genetics

CFM (OMIM 164210), a congenital malformation in which there is asymmetric deficiency in skeletal and soft tissue on one or both sides of the face, is the most frequently encountered form of facial asymmetry. CFM affects approximately 1 in 5600 births (Grabb, 1965). Individuals with features of CFM have been classified under a variety of different diagnoses (hemifacial microsomia, oculoauriculovertebral spectrum, facioauriculovertebral syndrome, first and second branchial arch syndrome, otomandibular dysostosis, Goldenhar syndrome, lateral facial dysplasia) attesting to the phenotypic variability of disorders associated with mandibular hypoplasia. Most often CFM is a sporadic condition with a recurrence risk of approximately 2% for future pregnancies, unless there is a known family history of microtia or CFM (Beleza-Meireles et al., 2014; Heike et al., 2014). Various causes, both environmental and heritable, have been studied, and for most, the cause is thought to be multifactorial.

Phenotype

CFM is primarily a syndrome of the first or second branchial arches, resulting in underdevelopment of the ear, temporomandibular joint, mandibular ramus and body, and mastication muscles. The affected ear may have an external soft-tissue malformation with or without preauricular tags and may be lower in position compared with the ear on the contralateral side. Hearing loss may result from maldevelopment of the ossicular chain and a stenotic or atretic external auditory canal. Second branchial arch defects can involve the facial nerve and muscles of facial expression, which can exacerbate the appearance of facial asymmetry. Even with bilateral facial involvement, there is usually asymmetry (Fig. 100.10A). The presence of microtia can be associated with significant risk of hearing loss on the affected side and increased risk of hearing loss in the contralateral ear (see Fig. 100.10B). Infants with CFM are often born small for their gestational age, and the perinatal history may include polyhydramnios due to fetal swallowing dysfunction.

A common classification system for CFM is the OMENS system, which characterizes the degree of involvement of facial structures: orbital distortion, mandibular hypoplasia, ear anomaly, nerve involvement, soft tissue deficiency (Gougoutas et al., 2007; Birgfeld et al., 2011). Extracraniofacial anomalies associated with CFM, including renal, cardiac, and vertebral anomalies, are common and will affect recommendations for screening and surveillance.

There can be extreme variability of phenotypic expression, ranging from isolated microtia to significant mandibular hypoplasia, bilateral microtia, clefting, and extracranial involvement. Isolated microtia may represent a *forme fruste* of CFM. Other craniofacial features include external auditory canal stenosis or atresia, unilateral

• **Fig. 100.10** (A, B) Infant with craniofacial microsomia, mandibular asymmetry, and left-sided microtia. (C) Child with an epibulbar lipodermoid and craniofacial microsomia.

macrostomia (transverse facial cleft leading to lateral displacement of the oral commissure and the most common form of orofacial clefting in CFM), cleft lip and/or palate, temporomandibular joint ankylosis, ankyloglossia, preauricular or facial pits (most common in the distribution of the facial nerve), midface hypoplasia and malocclusion, epibulbar lipodermoids (see Fig. 100.10C), microphthalmia, eyelid and ocular colobomas, facial palsy, and seventh nerve paresis and other cranial nerve palsies. Goldenhar syndrome has historically been described as a subgroup variant of CFM characterized by vertebral anomalies and epibulbar dermoids in addition to the ear and jaw findings. In CFM, deficient growth of the hypoplastic mandible and the compensatory growth of the contralateral maxilla and zygoma contribute to significant facial asymmetry that progresses with growth. Conversely, facial and skull asymmetry caused by deformation (intrauterine or postnatally with plagiocephaly and torticollis) will often reduce with time, repositioning, and treatment of torticollis.

Other Branchial Arch Malformations

Moebius Syndrome

Moebius syndrome (OMIM 157900) is a rare congenital condition affecting approximately 2000 people worldwide (Broussard and Borazjani, 2008). The sixth and seventh cranial nerves are universally affected. Sixth nerve palsy leads to inability to abduct the eyes beyond the midline. This is usually bilateral but may be unilateral or asymmetric. Paralysis of facial muscles results from the seventh nerve palsy. While newborns may have a “masklike facies,” the presentation may not be recognized in the newborn period (McKay et al., 2016). Feeding difficulties may result from swallowing and sucking problems, aspiration, and palatal weakness related to more widespread cranial nerve involvement. There have been associations with chest wall abnormalities, including absence of the pectoralis muscle, suggesting a pathogenic relationship with the Poland anomaly (OMIM 173800). Exposure conjunctivitis and keratopathy can occur in children with facial paralysis and lagophthalmos and should be prevented with ocular lubricants. Limb defects occur in half of children with Moebius syndrome, most commonly talipes deformity; however, transverse limb anomalies are also seen. Individuals with hypoglossia–hypodactylia or Hanhart syndrome can have severe limb deformities, ankyloglossia, and temporomandibular joint ankylosis, in addition to Moebius syndrome–like features and micrognathia, and are at risk of significant swallowing dysfunction and airway compromise (Yasuda et al., 2003).

Treacher Collins Syndrome

TCS is most commonly an autosomal dominant disorder of craniofacial development that affects approximately 1 in 50,000 live births (Rovin et al., 1964). As in CFM, the tissues affected in TCS arise from the first and second branchial arches. The major clinical features of TCS include hypoplasia of facial bones (particularly the mandible and zygoma), external ear anomalies or microtia, external auditory canal atresia, bilateral conductive hearing loss, lateral downward sloping palpebral fissures, and lower eyelid colobomas (Fig. 100.11A–B). Hearing loss is present in up to 50% of individuals with TCS (Dixon et al., 2007). In severe cases the zygomatic arch may be absent and CP may occur. Extracraniofacial features are rare in TCS. Mutations in one of three genes *TCOF1*, *POLRIC*, and *POLR1D* are causative of TCS, and mutations in the *TCOF1* gene account for 71%–93% of affected individuals (OMIM 154500). Diagnosis of TCS is usually made clinically and can be confirmed with genetic testing (Katsanis and Jabs, 2012). In newborns with TCS, airway management may be required to address narrowing of the airway or extreme shortening of the mandible (see Fig. 100.11C). When compared with that in CFM, the mandibular hypoplasia in TCS is usually bilateral and symmetric, leading to increased risk of upper airway obstruction, increased need for tracheostomy, and risk of death in the neonatal period. Choanal atresia or stenosis and severe micrognathia with glossoposis can lead to airway obstruction in the infant with TCS (Katsanis and Jabs, 2012).

Intensive Care Unit Concerns

Mandibular hypoplasia in CFM can lead to upper airway obstruction that may be obvious on physical examination, presenting with stertor or stridor and increased work of breathing, or may be more subtle, as with snoring obstructive sleep apnea. Bilateral severe mandibular and malar involvement in TCS leads to airway obstruction at the level of nasopharynx and base of the tongue and substantial respiratory compromise.

Infants with CFM may have feeding difficulties that may be related to macrostomia affecting lip seal, palate dysfunction, or more commonly swallow coordination issues and dysphagia related to hypoglossal dysfunction and muscular and bony underdevelopment. Infants with Moebius syndrome may have cranial nerve palsies that affect swallow and oral coordination. These infants are at higher risk of aspiration and should be monitored clinically,

• **Fig. 100.11** (A) Infant with Treacher Collins syndrome (TCS), microtia, severe mandibular and zygomatic hypoplasia, and airway obstruction requiring tracheostomy. (B) An older child with TCS, downslanting palpebral fissures, eyelid colobomas, and bilateral microtia wearing a hearing augmentation device. (C) Three-dimensional reconstruction of TCS. Note the severe mandibular and zygomatic hypoplasia, which may lead to significant airway compromise. Also notable are the orbital defects seen in TCS.

especially if they are failing to thrive or developing any concerns for aspiration or lower respiratory tract disease.

Management

In newborns with suspected CFM, an evaluation for any associated anomalies should be undertaken. All children with external ear anomalies or any evidence of first or second branchial arch abnormalities should undergo a diagnostic hearing evaluation in the newborn period, with follow-up audiometry in the first year of life. If there is any hearing loss, ongoing monitoring of hearing is routine. It is also important to monitor ear health and eustachian tube function in the patent/hearing ear. CT to assess middle and inner ear anatomy is not recommended in the neonatal period. Consultation for ear reconstruction and atresia repair should occur by 4 years of age, although hearing amplification and aural habilitation in hearing loss can be initiated earlier.

Renal ultrasonography and cardiac examination (echocardiogram) should be undertaken in infancy to identify any serious structural

malformations. Ophthalmology consultation should be sought for appropriate management of epibulbar lipodermoids, colobomas (if present), and risk of exposure keratopathy. Malocclusion and dental issues will need to be addressed as the child gets older. Children should undergo cervical spine screening radiographs to identify vertebral defects in segmentation. If the newborn has no symptoms of cervical spine abnormality, screening four-view cervical spine radiographs can be deferred until the child is 2 to 3 years old, when cervical vertebrae are more easily imaged. Appropriate cervical spine imaging is recommended in children undergoing surgery before 2 years of age and children with head tilt or signs of vertebral anomalies.

Mild airway obstruction in CFM may be reduced or minimized with prone positioning. However, infants with severe bilateral mandibular hypoplasia may have significant airway compromise and require tracheostomy placement. In cases with significant airway compromise, referral to a craniofacial center to determine optimal and safe airway management should be pursued. For treatment of mandibular underdevelopment, surgery timing is dependent on

the degree of mandibular hypoplasia, mandibular growth, occlusion, and airway involvement. For children with severe hypoplasia of the mandible, bone grafting may be necessary for jaw reconstruction before mandible distraction. Oral feeding should be introduced when the airway is stable. Oral stimulation is important to prevent oral aversion. Given the risk of feeding difficulty and aspiration in infants with malformations of the first and second branchial arches, early consultation with both a dietitian and a feeding therapist is recommended.

CHARGE Syndrome

Epidemiology and Genetics

The term *CHARGE* (coloboma, heart defect, atresia choanae, retarded growth and development, genital hypoplasia, ear anomalies/deafness) was first coined by Pagon, given the observation that the associated malformations occurred more frequently together than one would expect on the basis of chance (Pagon et al., 1981). Over time, the facial features and associated malformations were better characterized as a syndrome, with mutations in at least one major gene described (OMIM 214800).

This multiple malformation condition has a prevalence of approximately 1 in 10,000 births (Blake and Prasad, 2006). Although multiple chromosomal aberrations have been reported in children with the phenotype of CHARGE syndrome, mutations in the *CHD7* gene account for 65%–70% of cases. When the diagnosis of CHARGE syndrome is suspected, molecular testing for mutations in the *CHD7* gene can be performed to confirm the diagnosis and provide more information to assist in counseling for the parents and the patient. For children in whom *CHD7* gene testing results are normal, evaluation for chromosomal abnormalities and copy number variants is possible with use of comparative genomic hybridization and single-nucleotide polymorphism array technology (Lalani et al., 2012).

Phenotype

The diagnosis of CHARGE syndrome is based on a combination of major and minor clinical criteria, but the diagnosis should be suspected in any neonate with any of the major characteristics: ocular coloboma (80%–90%), choanal atresia or stenosis (50%–60%), cranial nerve dysfunction or facial palsy (40%–90%, depending on which cranial nerve is involved), or characteristic CHARGE ears (90%–100%) (Lalani et al., 2012). As in other conditions with severe airway obstruction or swallowing dysfunction, polyhydramnios is commonly present prenatally when bilateral choanal atresia is present.

Distinctive ear anomalies (hypoplastic lobes, cupped or lop, position is often low set and posteriorly rotated) or deafness occurs in most individuals with CHARGE syndrome (Fig. 100.12). Hearing loss can be a combination of conductive and sensorineural hearing loss. Other craniofacial features include square face with malar flattening, broad forehead, facial asymmetry, pinched nostrils, full nasal tip, long philtrum, and CP (40%). Ocular colobomas can range from a coloboma of the iris to anophthalmia. Cardiac defects can be a major source of morbidity in infants with CHARGE syndrome and are found approximately 80% of the time. Conotruncal and aortic arch anomalies are the most common congenital heart defects, but atrioseptal defects, ventriculoseptal defects, patent ductus arteriosus, hypoplastic left-sided heart, and vascular rings have also been described.

• **Fig. 100.12** (A) Child with CHARGE syndrome with (B) classic ear malformation—hypoplastic lobes, cupped and low set.

Intensive Care Unit Concerns

The most important postnatal emergency in CHARGE syndrome is bilateral posterior choanal atresia (Blake et al., 2009). Neonate with bilateral choanal atresia will have breathing difficulty and cyanosis within the first hour of life. As with all forms of nasal obstruction, crying relieves the cyanosis because it allows the obligate nose breather to take in air through the mouth; feeding exacerbates respiratory distress. Left untreated, the newborn with bilateral choanal atresia can asphyxiate and die. Symptoms of bilateral choanal stenosis or unilateral atresia may not present until after the newborn period with chronic rhinorrhea or breathing problems associated with respiratory infections. Respiratory distress in a newborn with CHARGE syndrome is usually due to choanal atresia, but other features, including swallowing dysfunction and reflux, can contribute to aspiration and lower respiratory tract disease. These infants may also have micrognathia and glossoptosis, putting them at risk of airway obstruction at the level of the pharynx/hypopharynx. Infants with CHARGE syndrome may require multiple surgical procedures during the first year of life and are at increased risk of postoperative airway events (Blake et al., 2009; Bergman et al., 2010).

Cyanotic heart disease may present in the immediate newborn period because of tetralogy of Fallot, outflow tract anomalies, and interrupted aortic arch. Awareness and recognition of the association of CHARGE syndrome and congenital heart defects are crucial.

A significant cause of morbidity is feeding difficulty. Feeding and secondary growth problems are common in early infancy and may be attributed to swallowing dysfunction, pharyngeal incoordination, gastroesophageal reflux, and aspiration. Cranial nerve palsies (specifically cranial nerves V, IX, and X) may contribute to swallowing dysfunction, and tracheoesophageal fistula (TEF) contributes to aspiration risk. Although it is well described that infants with CHARGE syndrome who survive the newborn period are more likely to survive childhood, the risk of death in infancy remains. Male sex, bilateral choanal atresia, TEF, cyanotic heart disease, atrioventricular septal defects, CNS malformations, and ventriculomegaly have all been associated with reduced life expectancy in individuals with CHARGE syndrome (Tellier et al., 1998; Issekutz et al., 2005; Blake et al., 2009). A study of 77

individuals with CHARGE syndrome found mortality to be 13% (Issekutz et al., 2005).

Management

While the clinical needs will differ, some children with CHARGE syndrome will require intensive medical management and undergo multiple surgical interventions in infancy and early childhood. Early management targets airway stabilization and circulatory support. With this in mind, neonates with CHARGE syndrome require immediate evaluation of their airway and cardiac structure and function. An oral airway should be placed if bilateral choanal atresia is suspected. This can stabilize the airway by bypassing the choanal obstruction. Once the airway has been secured, a confirmatory CT scan of the nasal passages can be obtained; a CT of the temporal bones can be included in conjunction with the facial CT and may reveal the characteristic inner ear findings (Mondini malformation of the cochlea and/or absent or hypoplastic semicircular canals) of CHARGE syndrome. If the oral airway does not allow adequate air entry, endotracheal intubation may be required. In consultation with a pediatric otolaryngologist, transnasal stents may be placed to keep the nasal passages patent in choanal stenosis (and postoperatively after choanal atresia repair). Given the significant risk of cyanotic heart defects, an echocardiogram and cardiology consultation should be obtained to assist in management.

Infants with CHARGE syndrome or suspected CHARGE syndrome should also have audiologic and ophthalmologic evaluations in the neonatal period and should be referred to Birth to Three/early intervention services. Consultation with an immunologist and immune evaluation should occur for the individual with CHARGE syndrome and recurrent infections (Wong et al., 2015). Underdevelopment of the genitals and genitourinary anomalies may be present. If there is a concern for hypogonadism, the pituitary–gonadal axis can be evaluated in infancy and will help determine the option for sex steroid therapy. Screening renal ultrasonography should also be performed (Blake and Prasad, 2006).

Consultations with both a feeding specialist and a dietitian are recommended in the newborn period. If the findings of an oral feeding evaluation or videofluoroscopic swallow study are concerning for swallowing dysfunction or aspiration, supplemental tube feeding should be initiated. With prolonged feeding issues, gastrostomy tube feeding is often necessary. Infants with severe gastroesophageal reflux and/or aspiration risk may be candidates for Nissen fundoplication at the time of gastrostomy tube placement.

Macroglossia/Beckwith–Wiedemann Syndrome

Epidemiology and Genetics

The true prevalence of Beckwith–Wiedemann syndrome (BWS; OMIM 130650) is unknown, but it has been estimated that BWS affects 1 in 13,700 births (Thorburn et al., 1970). This is probably an underestimate, given that there are mild cases of BWS that go undetected. The genetics of BWS is complex and variable. Most cases are sporadic and may result from chromosomal rearrangement, mutations, or epigenetic effects (DNA methylation changes) affecting imprinted genes on chromosome band 11p15.5. Approximately 80% of individuals with features of BWS are found to have an 11p15.5 abnormality by clinically available testing (Shuman et al., 2016). Although there are no consensus criteria for diagnosis of BWS, the presence of macroglossia, overgrowth, and abdominal

wall defects suggests the diagnosis of BWS. As children with BWS are at risk of neoplasms in early childhood, recognition and diagnosis of BWS are consequential. Data suggest a possible link between imprinting disorders and assisted reproduction, and thus infants conceived by in vitro fertilization may be at higher risk of BWS (Maher et al., 2003). If there are features of BWS present or a family history of BWS, geneticists may recommend 11p15 methylation studies and chromosome microarray analysis to identify abnormalities of the 11p15 region. Although genetic testing can provide confirmation of diagnosis in 80% of individuals, clinical suspicion of the diagnosis is sufficient for initiation of medical management and tumor surveillance studies. Currently, the frequency of screening study recommendations is independent of the underlying molecular cause; however, this will likely change in the future as children with BWS due to a gain of methylation at imprinting center 1 and paternal 11p15 uniparental disomy have a higher risk of developing tumors (Mussa et al., 2016). At this time, initiation of screening studies and consultation with genetics are recommended (Brioude et al., 2013).

Phenotype

BWS is a disorder of overgrowth with multiple features, including macrosomia, macroglossia, visceromegaly (involving the kidneys, pancreas, liver, spleen, or adrenal glands), abdominal wall defects (including rectus diastasis, umbilical hernia, and omphalocele), hemihypertrophy (asymmetric overgrowth of one or more regions of the body), renal anomalies (structural anomalies and nephrocalcinosis), and adrenocortical cytomegaly (Fig. 100.13). Macroglossia is the most frequent and most obvious manifestation of BWS (present more than 95% of the time) (Elliott et al., 1994). Other craniofacial features include capillary nevus flammeus, metopic ridge, large fontanel, mandibular prognathism, prominent eyes, anterior earlobe linear creases, and posterior helical pits. Less common findings in BWS include CP, cryptorchidism, and cardiac defects (isolated cardiomegaly is more common than cardiomyopathy). The risk of embryonal tumors (Wilms tumor, hepatoblastoma, neuroblastoma, or rhabdomyosarcoma) in childhood is estimated to be 7.5%, of which 95% present in the first 8 years of life, leading to recommendations for tumor surveillance (Firth and Hurst, 2005).

Some features suggestive of BWS may be present prenatally, including polyhydramnios (caused by swallowing dysfunction), preeclampsia, fetal macrosomia, and a large placenta. Prematurity has been reported in 50% of births (Elliott et al., 1994), and in addition to complications of prematurity, the neonate with BWS may develop hypoglycemia and polycythemia.

Intensive Care Unit Concerns

Hypoglycemia due to hyperinsulinemia and islet cell hyperplasia occurs in up to 50% of neonates with BWS and usually develops in the first few days of life (Munns and Batch, 2001). It is critical to detect and treat hypoglycemia in any neonate with features of BWS to prevent seizures and brain injury. Polycythemia can occur and may need to be treated in the early neonatal period.

Obstructive airway symptoms may present in the newborn period if macroglossia is severe. However, airway obstruction more commonly presents later in infancy, outside the newborn period. The enlarged tongue can occlude the upper airway, leading to respiratory distress, apnea, and hypoxia. A large tongue can also contribute to feeding issues, dysphagia, and aspiration. Upper airway endoscopic evaluation by an otolaryngologist and an

• **Fig. 100.13** (A) Premature newborn with Beckwith–Wiedemann syndrome, macroglossia, and rectus diastasis. (B) Same child at 6 months of age. Macroglissia has increased, and he now has a tracheostomy.

overnight sleep study may help understand the severity of airway compromise and guide airway treatment.

Mortality among infants with BWS has been reported to be as high as 21% and is related to complications of prematurity and macroglossia (Shuman et al., 2010).

Management

Hypoglycemia in newborns should be managed according to standard protocols for treating neonatal hypoglycemia. If hypoglycemia persists or is refractory to therapy, additional biochemical testing and consultation with an endocrinologist should be considered (Roženková et al., 2015). Neonates with an omphalocele may require surgery in the first few days of life.

There is no definitive approach to the management of macroglossia. Airway obstruction may be lessened by the placing of the baby on the side or prone. If the infant requires endotracheal intubation, it is important to exercise caution, because macroglossia can affect visibility of airway structures. If macroglossia results in significant airway obstruction or prolonged intubation, tracheostomy may be needed as a temporizing measure to bypass the obstruction. Tongue growth will slow over time, and as jaw growth accelerates, airway compromise should decrease. Some children may benefit from surgical reduction of the tongue, which is usually performed between 2 and 4 years of age, but may be offered as early as 3 to 6 months at some centers.

Referrals to an infant feeding specialist and dietitian are recommended in the infant with severe macroglossia or if the infant is not gaining weight. Although some infants are able to feed orally, others will benefit from supplemental tube feeding.

Although cardiac defects are rare, it is important to perform a thorough cardiac evaluation, including electrocardiogram and echocardiogram if any cardiac abnormalities are suspected.

Surveillance for tumors begins in the neonate with BWS or at the time of diagnosis. Abdominal ultrasonography to assess the patient for organomegaly and baseline CT or MRI of the abdomen should be performed. Abdominal ultrasonography every 3 months is recommended through 8 years of age. In conjunction, staggered serial serum alpha fetoprotein measurements (every 6 to 12 weeks) are recommended through 4 years of age to assist early identification of hepatoblastomas before detection by screening ultrasonography.

Referral to a craniofacial team may be helpful in the management of the airway obstruction in BWS, including evaluation for tongue reduction and facial hemihypertrophy. A geneticist and genetic counselor may recommend genetic testing for confirmation of the diagnosis and/or recurrence risk counseling.

Frontonasal Dysplasia, Hypertelorism, Encephalocele

Embryology

Frontonasal dysplasia (FND; also known as *frontonasal malformation*, *median cleft face syndrome*, and *frontal nasal syndrome*) is a malformation resulting from abnormal morphogenesis of the frontonasal process. The development of the facial midline is abnormal, leading to ocular hypertelorism and associated craniofacial features. Most cases of FND are sporadic.

Phenotype and Genetics

FND has been defined phenotypically as containing two or more of the following craniofacial features: ocular hypertelorism; broadening of the nasal root; midline facial cleft affecting the nose, lip, or palate; unilateral or bilateral clefting of the alae nasi; hypoplastic nasal tip; anterior cranium bifidum; and a V-shaped frontal hairline

(Wu et al., 2007). Grading of hypertelorism is best achieved by measurement of the interpupillary distance. In a term newborn an interpupillary distance greater than 4.5 cm is considered hypertelorism (Jones et al., 2013). FND is a heterogeneous condition with genetic forms (OMIM 136760, OMIM 613451, OMIM 613456, associated with mutations in three *ALX* genes), sporadic forms without associated anomalies, and FND phenotype with associated pattern of malformations (subtype of FND) or known genetic syndrome such as craniofrontonasal syndrome (Wu et al., 2007; van den Elzen et al., 2014).

In addition to hypertelorism, eye anomalies, including epibulbar dermoids, colobomas, ptosis, nystagmus, or cataracts, may be present in FND and are associated with a more severe phenotype and an increased incidence of CNS abnormalities (Wu et al., 2007). Associated CNS manifestations include encephalocele, agenesis of the corpus callosum, and abnormal neuronal migration. Developmental delay is a significant risk, especially when there are CNS malformations. When FND is associated with extracephalic anomalies or when ocular hypertelorism is more severe, there is an increased association with cognitive impairment (Hennekam et al., 2010d). Frontonasal encephaloceles (and meningoceles) are the most common encephaloceles in FND (Fig. 100.14).

A subpopulation of patients with frontonasal malformation also have coronal craniosynostosis and variable skeletal and ectodermal defects and have an X-linked condition termed *craniofrontonasal syndrome* (CFNS, OMIM 304110). Similarly to FND, facial features include hypertelorism, frontal bossing, broad nasal bridge, and a bifid nasal tip. Children with CFNS often have significant facial asymmetry due to unicoronal synostosis. In this X-linked condition, females are affected more severely than males (and typically have hypertelorism and grooved nails), and mutations are detected in the *EFNB1* gene. Affected individuals usually have normal intelligence.

• **Fig. 100.14** Magnetic resonance imaging of an infant with frontonasal dysplasia and a midline cleft lip. The scan reveals a moderate-sized meningocele extending into the posterior nasopharynx. The *white arrow* points to midbrain meningocele coming through the cribriform plate; the *black arrow* points to the intraoral meningocele.

Intensive Care Unit Concerns

Intracranial abnormalities associated with FND may put the infant at risk of CNS manifestations such as hydrocephalus or seizures. If the pituitary gland is involved or deficient, as can be seen with HPE sequence, there can be serious endocrine abnormalities (as discussed in Orofacial Clefing). Also, frontonasal encephalocele may contribute to upper airway compromise at the level of the nasopharynx.

Management

In any infant with hypertelorism or features that raise suspicion for FND, awareness of potential underlying malformations is critical, and cranial imaging by CT scan or MRI should be considered. Instrumentation of the nose and mouth, including placement of a nasogastric tube or suction catheter, should be avoided or used with caution until the CNS anatomy has been delineated. Because infants with FND have a high incidence of frontonasal encephalocele or meningocele, placement of these catheters could lead to brain injury. If an infant with FND needs urgent or emergent endotracheal intubation, intraoral structures should be examined carefully to prevent injury to herniating CNS structures if they are present. Management of seizures or any electrolyte derangements should be managed as per the neonatal ICU standard protocol. Consultation with a craniofacial team, including specialists in ophthalmology, can be helpful in understanding the work-up and management (including potential surgical interventions) for individuals with FND.

Prenatal Screening for Fetal Face Anomalies

The exact role of fetal face examination with ultrasonography in a low-risk pregnancy is under evaluation. Routine obstetric surveillance includes a midtrimester anatomic ultrasound examination at 18 to 22 weeks' gestation. Most studies looking at the recognition rate and incidence of ultrasonographic diagnosis of orofacial clefing focus on this anatomic examination. Adequate evaluation of the facial structures with ultrasonography can be achieved by 16 to 17 weeks' gestation. The following facial features can be visualized with two-dimensional routine ultrasonography at 18 weeks' gestation with standard facial views (which include coronal images of the nose, lips, and orbits and sagittal profile views): orbital size and position, eye size, including microphthalmia and anophthalmia, shape of nose, nasal hypoplasia, length of the philtrum, clefts of the upper lip, frontal bossing, retrognathia, micrognathia, macroglossia, and soft tissue abnormalities. Cleft lip with or without CP can be detected by prenatal ultrasonography, whereas isolated CP, which is not typically associated with a cleft of the alveolus, may be obscured by the tongue, which has the same echogenicity as the secondary palate, thus making prenatal diagnosis of CPO more difficult. A retrospective study in a low-risk population demonstrated that routine prenatal ultrasonography with standard facial views performed at 18 weeks' estimated gestational age detected 93% of cases of cleft lip and palate, 67% of cases of isolated cleft lip, and 22% of cases of CPO (Cash et al., 2001). New and increasingly sensitive methods for identifying craniofacial differences prenatally are emerging (Tonni et al., 2015; Rubio et al., 2016). Although the diagnosis is not definitive, prenatal diagnosis is particularly valuable in allowing appropriate prenatal counseling (Maarse et al., 2015). Families who have the opportunity to meet members of a craniofacial team before delivery often appreciate having some understanding of what to

expect in the newborn period and are armed with knowledge to help their new baby receive the best care possible.

Common Neonatal Orthopedic Conditions

KLANE K. WHITE, MARYSE BOUCHARD, AND MICHAEL J. GOLDBERG

KEY POINTS

- Development dysplasia of the hip represents a spectrum of disease. Selective screening by physical examination and imaging is recommended.
- Most cases of congenital muscular torticollis resolve spontaneously. Physical therapy and surgery are reserved for recalcitrant cases.
- A variety of foot deformities are common and can be encountered in the neonate. Stretching, casting, or surgery may be required for resolution.
- Torsional and angular deformities of the lower extremities must be differentiated from physiologic variants. Asymmetry and rapid progression are the hallmarks of pathologic variants.
- Congenital vertebral anomalies result from failures of formation or segmentation of spinal elements. Spinal deformities such as scoliosis or kyphosis may ensue.

Although orthopedic afflictions of the newborn are generally not life threatening, they do have the potential to significantly impair functional performance, even when diagnosed and treated early. This chapter discusses the most commonly encountered of these orthopedic problems.

Developmental Dysplasia of the Hip

The term *developmental dysplasia of the hip* (DDH) encompasses a spectrum of disease from acetabular dysplasia, to hips that are located but unstable (femoral head can be moved in and out of the confines of the acetabulum), to frankly dislocated hips in which there is a complete loss of contact between the femoral head and acetabulum. DDH occurs in 11.5 of 1000 infants, with frank dislocations occurring in 1 to 2 per 1000 ([Committee on Quality Improvement, Subcommittee on Developmental Dysplasia of the Hip, 2000](#); [Guille et al., 2000](#)). Studies have suggested that breech positioning at delivery, family history of DDH, limited hip abduction, talipes, female sex, swaddling, large birth size, and first born have all been associated with a higher probability of finding DDH ([American Academy of Orthopedic Surgeons, 2014](#)). The left hip alone is affected in 60% of infants, the right hip alone is affected in 20% of infants, and both hips are affected in 20% of infants ([Guille et al., 2000](#)).

Dislocations can be divided into two groups: syndromic and typical. *Syndromic* dislocations are most frequently associated with neuromuscular conditions such as myelodysplasia and arthrogryposis or with syndromes such as Larsen syndrome. Syndromic dislocations probably occur between week 12 and week 18 of gestation ([Committee on Quality Improvement, Subcommittee on Developmental Dysplasia of the Hip, 2000](#)). *Typical* dislocations occur in otherwise healthy infants in the third-trimester prenatal period or postnatally.

Congruent reduction and stability of the femoral head are necessary for normal growth and development of the hip joint. The natural history of untreated DDH is controversial because newborn instability may resolve or progress to painless dislocation. In cases that progress to subluxation, individuals have significantly increased risk of developing precocious arthritis with moderate to severe hip pain as young adults ([Wedge and Wasylenko, 1979](#); [Cooperman et al., 1983](#)). This pain can be debilitating and the reconstruction difficult. Early detection and treatment of DDH are therefore important in avoiding the devastating sequelae of a late diagnosis.

There are no pathognomonic signs of a dislocated hip. The physical examination requires patience on the part of the examiner and may be facilitated by having the baby feed from a bottle. Evaluation for asymmetry is perhaps the most important key to the evaluation for DDH, although asymmetry is not typically evident in bilateral dislocations. The presence of asymmetric abduction is suggestive of a dislocation, as is a Galeazzi sign. The presence of asymmetric thigh folds may be indicative of DDH but often occurs in unaffected infants. The Galeazzi sign is elicited with the baby placed supine on an examining table so that the pelvis is level, with the hips and knees flexed to 90 degrees. With the baby's hips in neutral abduction, the examiner determines if the knees are at the same height. If one femur appears shorter than the other, the hip may be dislocated posteriorly ([Fig. 101.1](#)). Limitation of hip abduction in babies older than 12 weeks is the most reliable examination finding suggestive of DDH. Adduction of 30 degrees and abduction of 75 degrees should be possible in most newborns. Side-to-side variations should be noted. Each of these signs, individually or in combination, may serve to increase the index of suspicion of the examiner and lower the threshold for further diagnostic studies or referral to a pediatric orthopedist.

There are two common ways of assessing hip stability in the newborn ([Fig. 101.2](#)). The Ortolani test is performed on one leg

at a time, with the calm newborn supine on the examining table. The index and middle fingers of the examiner are placed along the greater trochanter, while the thumb is placed on the medial aspect of the thigh. The pelvis is stabilized by the placing of the thumb and ring or long finger of the opposite hand on top of both anterior iliac crests simultaneously. Alternatively, the opposite thigh may be held in the same manner as the examined side, thus

• **Fig. 101.1** Presence of Galeazzi sign.

stabilizing the pelvis. The hip is flexed to 90 degrees and gently abducted while the leg is lifted with the hip in neutral external/internal rotation. A palpable clunk is felt as the dislocated femoral head reduces into the acetabulum. This finding is reported as the Ortolani sign (positive result on the Ortolani test). The Barlow test is an attempt to dislocate or subluxate a located but unstable hip. The thigh is held and the pelvis stabilized in the same manner as for the Ortolani test. With the hip in neutral external/internal rotation and at 90 degrees of flexion, the leg is then gently adducted with a mild posteriorly directed pressure applied to the knee. A palpable clunk or sensation of posterior movement constitutes a positive result (i.e., the Barlow sign). Each hip should be examined separately. High-pitched clicks are frequently elicited with hip range of motion. These sounds are most frequently attributed to snapping of the iliotibial band over the greater trochanter and are not associated with dysplasia (Bond et al., 1997). With progressive soft tissue contractures, both the Ortolani test and the Barlow test become unreliable after 3 months of age.

Imaging of the immature hip can be a valuable adjunct to the physical examination. An anteroposterior (AP) radiograph of the pelvis can be difficult to interpret before the age of 4 to 5 months. The femoral head is composed entirely of cartilage until the secondary center of ossification appears. Before the appearance of the secondary center, ultrasound examination is the method of choice for visualizing the cartilaginous femoral head and acetabulum. Static ultrasound images allow visualization of acetabular and femoral head anatomy, while the complementary dynamic images give information on the stability of the hip joint (Graf, 1984; Clarke et al., 1985). The primary limitation of hip ultrasonography is that the results are dependent on the experience and skill of the operator, especially when performed within the first 3 weeks after birth (Marks et al., 1994). For these reasons ultrasonography is

• **Fig. 101.2** Assessing hip stability. (A) Ortolani-positive hips are those where the dislocated hip can be relocated. (B) Barlow-positive hips are reduced but can be dislocated.

recommended as an adjunct to clinical evaluation rather than as an independent screening tool ([Committee on Quality Improvement, Subcommittee on Developmental Dysplasia of the Hip, 2000](#)). Studies conducted before 4 weeks after birth may be useful for confirming equivocal physical examination findings and for monitoring treatment of hips with known dislocations. Clinicians must be aware, however, that ultrasound images in this age group often reveal minor degrees of dysplasia that usually resolve spontaneously and may lead to overtreatment of physiologic hip variations. Ultrasonography is the technique of choice for assessment of infants at high risk of DDH after 4 to 6 weeks of age and again is useful in following up the results of intervention. After 4 months of age, the gold standard remains the AP radiograph of the pelvis.

All newborns should be screened for DDH by a properly trained healthcare provider by physical examination. Risk factors for DDH should be determined by the treating physician. A Cochrane review found that neither universal nor targeted ultrasound screening strategies have been demonstrated to improve clinical outcomes, including the incidence of late-diagnosed DDH and need for surgery ([Shorter et al., 2013](#)). Adding further confusion to the debate over the approaches to optimal DDH screening procedure is a report by the US Preventive Services Task Force, which found “insufficient evidence” to recommend *any* routine DDH screening, including physical examination ([Shipman et al., 2006](#)). This recommendation was based on the lack of clear evidence for the efficacy of infant screening to reduce the incidence of late-presenting DDH. In response to these findings, the American Academy of Orthopedic Surgeons (endorsed by the American Academy of Pediatrics, the Pediatric Society of North America, and the Society for Pediatric Radiology) has published a revised clinical practice guideline to aid in the early diagnosis of and initiation of appropriate intervention for DDH ([Mulpuri et al., 2015](#)). These recommendations are summarized as follows:

1. Universal ultrasound screening. Moderate evidence supports not performing universal ultrasound screening of newborn infants.
2. Evaluation of infants with risk factors for DDH. Moderate evidence supports performing an imaging study before 6 months of age in infants with one or more of the following risk factors: breech presentation, family history, or history of clinical instability.
3. Imaging of the unstable hip. Limited evidence supports that the practitioner might obtain an ultrasound image in infants younger than 6 weeks of age with positive instability examination findings to guide the decision to initiate brace treatment.
4. Imaging of the infant hip. Limited evidence supports the use of an AP radiograph of the pelvis instead of an ultrasound image to assess DDH in infants beginning at 4 months of age.
5. Surveillance after normal findings from an infant hip examination. Limited evidence supports that a practitioner reexamine infants previously screened as having normal hip examination findings on subsequent visits before 6 months of age.
6. Stable hip with ultrasound imaging abnormalities. Limited evidence supports observation without a brace for infants with a clinically stable hip with morphologic ultrasound imaging abnormalities.
7. Treatment of clinical instability. Limited evidence supports either immediate or delayed (2 to 9 weeks) brace treatment for hips with positive instability examination findings.
8. Type of brace for the unstable hip. Limited evidence supports use of the von Rosen splint over Pavlik, Craig, or Frejka splints for initial treatment of an unstable hip.

9. Monitoring of patients during brace treatment. Limited evidence supports that the practitioner perform serial physical examinations and periodic imaging assessments (ultrasound or radiograph depending on age) during management for unstable infant hips.

If there are no risk factors, then serial examinations are recommended according to a standard periodicity schedule until the child is 6 months old. If during these periodic visits physical findings raise suspicion of DDH, or if a parental concern suggests hip disease, confirmation is recommended by an expert physical examination, by referral to a pediatric orthopedist (or other practitioner with expertise in medical and surgical management of newborn hip disease), or by age-appropriate imaging. When a positive Ortolani or Barlow test is present at birth and persists beyond the usual age of spontaneous resolution (2 to 9 weeks), the infant should be referred to an orthopedist for management. However, if the positive Ortolani or Barlow test disappears, then age-appropriate imaging (ultrasonography at 6 weeks or radiograph by 6 months) is warranted. If the baby has positive risk factors, such as breech positioning at birth or a family history but stable hip examination findings, then age-appropriate imaging is recommended (ultrasonography at 6 weeks or radiograph at 6 months).

Although previously recommended, triple diapering is not an accepted form of treatment in DDH, and communication between providers is encouraged if the practitioner examining the newborn in the hospital is different from the 2-week follow-up examiner. Despite newborn screening programs, 1 in 5000 will have a dislocated hip detected at 18 months of age or older ([Dezateux and Godward, 1995](#)). It is important to appreciate that not all dislocated hips are present at birth, and not all hips dislocated at birth are detectable in the newborn period.

Treatment of DDH is dependent on the age at presentation. For children aged 0 to 6 months, a reducible hip is treated in a Pavlik harness or other appropriate orthosis. Patients with modest ultrasonographic abnormalities but stable hip examination findings can be monitored, as normalization can be expected without treatment ([Sucato et al., 1999](#)). The Pavlik harness is a dynamic orthosis that allows the infant to actively move the hips through a sphere of motion that encourages deepening and stabilization of the acetabulum ([Fig. 101.3](#)). The harness is applied as soon as possible after the diagnosis of DDH is made. The length of treatment is dependent on the age at presentation. Progress is judged by serial physical examinations and static and dynamic ultrasonography. In the case of a frankly dislocated hip, treatment is abandoned if no improvement is noted within 4 weeks of splint application. Closed reduction under general anesthesia, usually with arthrographic evaluation and subsequent spica casting, is then attempted at 4 to 5 months of age ([Luhmann et al., 2003](#)). For a persistently irreducible dislocation, which is unusual in the 0 to 6-month age group, open operative reduction of the hip with subsequent spica casting is undertaken. The success of Pavlik harness treatment is variable and correlates with the severity of the hip dysplasia. Treatment is successful in nearly 100% of stable hips, greater than 90% of dislocatable (Barlow-positive) hips, 61%–93% of dislocated but reducible (Ortolani-positive) hips, and only 40% of irreducible dislocations ([Viere et al., 1990](#); [Hangen et al., 1995](#); [Sucato et al., 1999](#); [Lerman et al., 2001](#); [Swaroop and Mubarak, 2009](#)).

Torticollis

Congenital muscular torticollis (CMT) manifests itself at birth or soon thereafter and is the most frequent cause of wryneck. However,

• **Fig. 101.3** The Pavlik harness. Lightweight orthotic, useful in treatment of neonatal DDH. The device holds the hip in flexion and abduction, promoting optimal positioning of the femoral head in the acetabulum. Excessive flexion and abduction should be avoided.

other conditions, some more serious, may cause torticollis. These include congenital anomalies of the vertebra and skull (e.g., Klippel–Feil syndrome, hemivertebrae, basilar invagination, craniosynostosis) (Hensinger et al., 1974; Dubousset, 1986; Raco et al., 1999), abnormalities of the central nervous system (e.g., syringomyelia, tumors) (Kiwak et al., 1983), Chiari malformations (Dure et al., 1989), ocular abnormalities (Bixenman, 1981); pharyngeal abscess, and gastroesophageal reflux (e.g., Sandifer syndrome) (Ramenofsky et al., 1978). Patients with CMT can be divided into those who demonstrate a sternocleidomastoid muscle (SCM) “pseudotumor,” those with tightness or fibrosis of the SCM without pseudotumor (termed *muscular torticollis*), and those with all of the characteristic features of congenital torticollis without evidence of contracture or fibrosis of muscle (termed *postural torticollis*) (Cheng et al., 2001).

CMT has been estimated to occur in 0.3%–2.0% of live births (Cheng et al., 2001). It is usually discovered between 6 and 8 weeks after birth. The infant presents with a cock robin appearance, with the head tilted toward and the chin rotated away from the affected SCM. Twenty percent to 30% of patients will have a palpable pseudotumor present in the middle to inferior aspect of

the affected SCM, which spontaneously regresses with time, leaving a fibrous band (Herring, 2002). More than half will have facial asymmetry. The left and right SCMs are affected in equal proportions. CMT probably results from ischemia within the SCM, leading to fibrosis (Davids et al., 1993). The cause of the ischemia is unknown, but intrauterine crowding may play a role, inasmuch as some authors have reported an association of torticollis with other deformations, such as DDH and metatarsus adductus (Morrison and MacEwen, 1982; Tien et al., 2001).

Excellent results with a manual stretching program can be attained in children first seen before 1 year of age (Morrison and MacEwen, 1982; Carenzio et al., 2015). Initially, the parents are instructed in the technique of stretching the contracted SCM by rotating the infant’s chin toward the affected SCM while simultaneously tilting the head away from it. This is completed 10 times each session and held for a count of 10 and done at least 10 times per day. Unfortunately, adherence may be an issue. If the child fails to improve substantially within 3 to 4 weeks, a physical therapist is enlisted to see the child two or three times weekly to supervise the program and reinforce the home therapy. Additionally, the parents are instructed to configure the infant’s crib and toys in such a manner as to encourage active rotation toward the involved side.

There is no justification to undertake surgery in any child younger than 1 year or in any child who has not completed a minimum of 6 months of therapy (Morrison and MacEwen, 1982; Cheng et al., 2001). In a prospective study of 821 children with muscular torticollis, only 8% of patients with a history of a pseudotumor, and 3% of those without, required surgical intervention following a well-structured stretching program (Cheng et al., 2001). Because of the difficulty of monitoring exercise programs, because parental adherence is always in question, and because surgical intervention is infrequent, it is possible that in many patients resolution is spontaneous. No patients with postural torticollis require surgery. Risk factors for surgery include late initial presentation, presence of a pseudotumor, and rotation deficit of greater than 15 degrees.

The timing of surgical intervention remains controversial. In patients with significant plagiocephaly and facial asymmetry, surgery should be considered just before 2 years of age so as to maximize the chance for complete remodeling. For those with either no or mild facial asymmetry, good to excellent results can be expected with surgery up to 6 years of age (Ling, 1976). Acceptable results are reported as late as 12 years of age, but the ability to remodel facial asymmetry appears diminished (Lee et al., 1986). More recent literature suggests good surgical outcomes in neglected CMT even after 15 years of age (Kim et al., 2015). Surgery entails either release or lengthening of the SCM through cosmetically pleasing incisions (Ferkel et al., 1983). The use of a molded helmet to promote facial and skull remodeling is common in some centers. Prospective studies that establish the effectiveness of helmets are lacking.

A less frequent cause of congenital torticollis is osseous fusion between bones in the cervical spine. These fusions may be between the skull and C1 and/or C2 or in the lower cervical spine. They result from failure of the bones to properly segment during embryogenesis. These abnormalities, in combination with a low posterior hairline and a short webbed neck with limited range of motion and head tilt, constitute the triad referred to as *Klippel–Feil syndrome* (Copley and Dormans, 1998). These congenital bone fusions can range from involvement of two segments to involvement of the entire cervical spine. Colloquially, Klippel–Feil syndrome has come to refer to any congenital malformation in the cervical

spine with or without other elements of the triad. In infants and young children the neck may remain quite flexible despite the bone abnormalities. In a newborn with torticollis who does not improve with passive stretching exercises, radiologic evaluation is mandatory. Cervical spine radiographs are not recommended in all patients initially presenting with neonatal torticollis, as these radiographs are quite difficult to interpret in this age group because of the predominance of cartilage in the bones of the neck. Furthermore, many neonates would be subjected to unnecessary ionizing radiation.

The natural history of Klippel–Feil syndrome in most cases is quite favorable, requiring nothing more than periodic observation. In patients with severe involvement, however, the consequences of this disorder can include early spondylosis with the development of pain or stenosis, the development of progressive torticollis and scoliosis, and the occurrence of neurologic compromise and sudden death secondary to even minimal trauma (Herring, 2002). Despite these potentially devastating sequelae, the greatest advantage of early detection of Klippel–Feil syndrome is in being alerted to commonly associated disorders, including congenital heart disease (14%–29%), renal anomalies (25%–35%), scoliosis (60%), audiologic anomalies (80%), including deafness (15%–35%), synkinesis (15%–20%), and, less commonly, posterior fossa desmoid tumors (Muzumdar and Goel, 2001; Herring, 2002). The recognition of a Klippel–Feil anomaly should prompt a thorough evaluation for these associations. Treatment of Klippel–Feil syndrome most often involves periodic observation with activity modification. In the face of progression of deformity or severe deformity, spinal fusion may be warranted.

Sandifer syndrome (gastroesophageal reflux) can also cause a torticollis. With this syndrome the torticollis is intermittent and may change direction, and there is no tightness of the SCM, with normal findings on radiographs (Ramenofsky et al., 1978).

Hemiatlas, or the failure of formation of a portion of the first cervical vertebra, is also a rare cause of torticollis (Dubousset, 1986). In the infant the neck may be quite flexible and the torticollis passively correctable. An open-mouth (odontoid view) cervical spine radiograph reveals this deformity. If the torticollis is progressive or severe, gradual correction of the deformity with a halo vest followed by posterior occiput to cervical spine fusion is necessary. Other potential causes of torticollis in the neonate include central nervous system tumors and syringomyelia. If radiographs appear normal, a thorough neurologic examination and referral to a neurologist are recommended.

Foot Deformities

Congenital deformities of the foot are relatively common but often overlooked in newborns. Consequently, the true incidence of the milder, self-limited deformities is unknown. For identification purposes, congenital foot abnormalities can be divided into those that result in the toes pointing upward (calcaneovalgus, congenital vertical talus), those that result in the toes pointing inward (metatarsus adductus, clubfoot), and those with too many toes or toes stuck together (polydactyly, syndactyly).

Calcaneovalgus is thought to be a postural deformity secondary to intrauterine positioning in which the dorsum of the foot is, or can be, directly apposed to the anterior aspect of the leg (Fig. 101.4). Plantar flexion of the foot is often limited from contracture of the anterior ankle and lateral soft tissues. The estimated incidence of calcaneovalgus is 0.4 per 1000 to 1 per 1000 live births (Wynne-Davies, 1964; Nunes and Dutra, 1986). It appears to be more

• **Fig. 101.4** Calcaneovalgus foot. (From Pediatric Pes Planus JAAOS Oct. 2015, Bouchard M, Mosca V. Flatfoot deformity in children and adolescents: surgical indications and management. *J Am Acad Orthop Surg.* 2014;22:623–632.)

• **Fig. 101.5** Congenital vertical talus. (From Pediatric Pes Planus JAAOS Oct. 2015, Bouchard M, Mosca V. Flatfoot deformity in children and adolescents: surgical indications and management. *J Am Acad Orthop Surg.* 2014;22:623–632.)

common in girls and after breech deliveries (Nunes and Dutra, 1986). There may be an increased association with hip dysplasia, so a thorough hip examination is warranted, as outlined in Developmental Dysplasia of the Hip (Paton and Choudry, 2009). Complete resolution with gentle stretching exercises conducted by the parents can be achieved, although complete resolution generally occurs spontaneously by 3 to 6 months of age. In the more severe calcaneovalgus feet where the ankle cannot be plantar flexed past the neutral position, serial casting to facilitate correction is often required. Calcaneovalgus may be seen in conjunction with external rotation of the tibia and posteromedial bowing of the tibia. A deformity that fails to resolve mandates referral to a pediatric orthopedist.

Calcaneovalgus needs to be differentiated from congenital vertical talus, a rarer condition that is frequently associated with neuromuscular conditions and syndromes such as arthrogryposis and

• **Fig. 101.6** The appearance of the foot with metatarsus adductus. (From the private collection of Dr. Vincent S. Mosca, Department of Orthopedics and Sports Medicine, Seattle Children's Hospital, Seattle, WA.)

spina bifida (Hoffinger, 1996). In congenital vertical talus the hindfoot is fixed in equinus (plantar flexion), giving the sole of the foot a characteristic “rocker bottom” appearance because of dorsal dislocation of the midfoot though the talonavicular joint (Fig. 101.5). Treatment during infancy consists of serial casting to stretch dorsal soft tissues and reduce the midfoot, followed by limited surgical release if needed, pinning of the talonavicular joint, and Achilles tenotomy (Dobbs et al., 2006). Most children have surgery between 6 and 12 months of age, and best outcomes are achieved when surgery is performed before age 2 years (Stricker and Rosen, 1997). When casting fails to reduce the midfoot, more extensive surgical releases are required.

The two common neonatal foot deformities resulting in medial deviation of the toes are metatarsus adductus and talipes equinovarus (clubfoot). Metatarsus adductus is present at birth but frequently diagnosed later during the first year of life. It has been estimated to occur in 1 in 100 births (Widhe et al., 1988). The condition is thought to result from intrauterine crowding. Characteristic features include a concave medial border of the foot with a curved lateral border, a “bean-shaped” sole of the foot, a higher-than-normal-appearing arch, and a neutral heel (Fig. 101.6; Hart et al., 2005). Metatarsus adductus can be classified into cases that undergo passive correction and those that do not. Feet in which passive correction is possible are best left alone and will improve spontaneously. Feet in which passive correction is not possible (the curved lateral border cannot be straightened) should be treated with manipulation and serial casting by age 6 to 9 months. The corrections can then be maintained with reverse or straight-last shoes if necessary. Operative treatment should be considered only in children older than 3 years who have a rigid deformity and have failed to respond to a casting program (Weinstein, 2000).

The term *clubfoot* describes a foot with hindfoot equinus and adduction and supination of the forefoot (Fig. 101.7). Clubfoot deformities range from mild to severe and occur in 1 in 1000 to 2 in 1000 live births (Herring, 2002). A risk factor for clubfoot is early amniocentesis (11 to 13 weeks' gestation), which is hypothesized to cause decreased fetal movement during a critical

• **Fig. 101.7** The appearance of an untreated newborn clubfoot. (From the private collection of Dr. Vincent S. Mosca, Department of Orthopedics and Sports Medicine, Seattle Children's Hospital, Seattle, WA.)

phase of foot development (Tredwell et al., 2001). Although the cause of clubfoot remains unproven, there appears to be dysplasia of all osseous, muscular, tendinous, cartilaginous, skin, and neurovascular tissues distal to the knee in the affected limb.

The mild, “postural” clubfoot appears to represent a packaging problem due to intrauterine positioning. This deformity is passively correctible, lacks deep medial creasing, demonstrates minimal or no calf atrophy, and resolves spontaneously or responds quickly to a stretching and casting regimen. At the opposite end of the spectrum is the arthrogryptic or neuromuscular clubfoot that demonstrates severe rigidity; absence of skin creases, suggesting early in utero affliction; and failure to respond to nonoperative therapies. Between these two extremes lies the classic, idiopathic clubfoot deformity. The typical clubfoot demonstrates a deep, single medial skin crease, curved lateral border with a high arch, and rigid varus and equinus of the heel with a deep, single, posterior skin crease (Noonan and Richards, 2003). This gives the foot its “down and in” position and toes pointing to the midline. In unilateral cases the affected limb has a smaller foot and calf circumference (see Fig. 101.7).

All clubfoot deformities should be referred to a pediatric orthopedist for treatment. Initial treatment for all cases of congenital clubfoot is nonoperative. Untreated clubfoot has a poor natural history, with development of early degenerative changes in the foot joints. Historically, clubfoot was treated with early and extensive surgical correction. The long-term results, however, are poor, with high recurrence rates (Weinstein, 2000). Consequently, this approach was abandoned, and surgeons began advocating nonoperative methods of clubfoot correction (Kite, 1964; Seringe and Atia, 1990; Ponseti, 1996). These programs differ in the specifics of treatment but share a labor-intensive approach. Although many forms of nonoperative clubfoot treatment exist, the Ponseti method of cast correction has achieved preeminence in this regard. Studies show excellent mid-term to long-term results with decreased stiffness (Ponseti, 1992).

The Ponseti method uses a specific set of manipulations and serial corrective long-leg casts, followed by a prolonged period of bracing. Treatment is ideally commenced within the first few weeks after birth, but successful treatment is commonly achieved when treatment is initiated up to 1 year of age (Dobbs et al., 2004). We prefer to initiate treatment 1 to 2 weeks after discharge from the hospital to allow parental adjustment for the new child in their lives. Every 5 to 7 days, manipulation of the foot is performed with passive stretching, and the correction is maintained with a new long-leg cast, with an average of four to five casts in the idiopathic clubfoot (Dobbs et al., 2006). This is followed by

• **Fig. 101.8** Development of the tibiofemoral angle during growth. (Data from Salenius P, Vankka GK. The development of the tibiofemoral angle in children. *J Bone Joint Surg Am.* 1975;57:259-261.)

percutaneous Achilles tenotomy in most patients and a further 3 weeks of casting. Children are then placed into a foot abduction orthosis full-time for a period of 3 months and then part-time, while sleeping, until approximately age 4 years.

The “French functional method” has also been successfully duplicated in at least one US hospital with good results (Herring, 2002; Faulks and Richards, 2009). This method necessitates daily manipulations by a trained physical therapist for 8 weeks, with the addition of continuous passive motion during the first 4 weeks. This is followed by strapping and continued bracing.

The Ponseti and the French “nonoperative” methods both frequently use Achilles tenotomy and, at times, tendon transfers to attain the ultimate desired result. Recurrences of deformity are common (16%–37%), requiring further casting. A smaller percentage of patients (8%–16%) require surgical release of the hindfoot to various degrees (Faulks and Richards, 2009; Janicki et al., 2009).

Torsional and Angular Deformities of the Lower Extremities

Torsional and angular deformities of the legs constitute the most frequent nontraumatic reason for referral to a children’s orthopedist. Torsional deformities of the lower extremities rarely come to the attention of the physician before the child reaches walking age.

Occasionally a neonate demonstrates bowing of the legs, or genu varum, of a sufficient degree to concern the parents. The true incidence of genu varum is unknown, but in our experience it is extremely common. The overwhelming majority of cases resolve spontaneously, with a small minority of affected children manifesting a pathologic condition. Genu varum and internal tibial torsion

are nearly universal in neonates and spontaneously resolve between 2 and 3 years of age. Internal tibial torsion imparts an appearance of bowing to the tibia (Brooks and Gross, 1995). This is often concerning to both the parent and the physician.

Genu varum is physiologic up to the age of 2 years. Salenius and Vankka (1975) documented the tibiofemoral angles both clinically and radiographically in 979 children on the basis of 1408 examinations between birth and 16 years of age. They noted that newborns demonstrate a mean varus alignment of 15 degrees, which increases and becomes maximal at 6 months of age and then decreases to neutral at approximately 18 months. The maximum valgus (knock knees) of 12 degrees is then achieved by 3 to 4 years. By age 7 years, normal adult valgus alignment is achieved (Fig. 101.8). Natural history studies have demonstrated that physiologic genu varum is a self-limited process. Even genu varum with angulation greater than 30 degrees has been shown to undergo correction spontaneously with growth (Heath and Staheli, 1993).

Management of physiologic genu varum and tibial torsion consists of serial observation, reassurance, and parental education. Treatment with orthotics such as the Denis Browne splint is not indicated and in fact may be harmful to the ligaments of the knee.

Physical examination should include evaluation of the torsional profile (Staheli, 1977), which includes measurements of internal and external rotation of the hips and the thigh-foot angle. Measurement of the thigh-foot angle is performed with the child in the prone position comparing the axes of the sole of the foot with the thigh and is an indicator of tibial torsion. The examiner should also look for evidence of rhizomelic shortening and genu varum, which may herald a diagnosis of achondroplasia or other skeletal dysplasia.

It is important to note whether onset of the varus of the lower extremities is gradual or abrupt and if the deformity can be localized to the distal part of the femur, the proximal part of the tibia, or the midportion of the tibia. Radiographs are indicated only with asymmetric deformities, with short stature, or in infants with progressive deformities. Photographs are the preferred method of follow-up evaluation for progression.

Considerations in the differential diagnosis of genu varum include focal fibrocartilage dysplasia, skeletal dysplasias such as achondroplasia, posttraumatic physal growth arrests, osteogenesis imperfecta (OI), and metabolic bone disease such as vitamin D-resistant rickets, renal osteodystrophy, and tibia vara (infantile Blount disease). Blount disease is bilateral in 80% of affected children and does not occur before walking age, and most clinicians agree that this diagnosis cannot be made before 2 years of age.

Focal fibrocartilaginous dysplasia (FFD) involving the medial aspect of the proximal tibial metaphysis is a relatively rare cause of genu varum in the newborn and infant. It was first reported by Bell et al. (1985) and continues to be recognized in scattered case reports. The pathophysiologic basis for the disease may be abnormal development of fibrocartilage at the insertion of the pes anserinus (medial hamstring tendons). FFD presents before 1 year of age with unilateral bowing of the tibia that has prompted radiologic evaluation. The radiographs demonstrate a lytic defect in the proximal medial metaphysis of the tibia with surrounding sclerosis. The natural history of the deformity is that of progression until 2 years of age, with subsequent resolution by 4 years of age. During the progression the deformity can become quite pronounced and unsettling. Up to 1 cm of tibial length discrepancy is likely. Use of orthotics is not indicated. Surgery is indicated only in patients older than 4 years without evidence of spontaneous resolution (Zayer, 1980).

Tibial bowing can also occur in the sagittal plane. There are two major types of bowing distinguished by the direction of the apex of the bow. Posteromedial bowing has been previously described in conjunction with calcaneovalgus foot position in the neonate. Its cause is unknown, but numerous hypotheses have been proffered, including intrauterine fracture with malunion and in utero malpositioning with subsequent growth retardation and soft tissue contractures (Thompson, 2001). The deformity is unilateral and evident at birth. There is an associated calcaneovalgus foot deformity. Other features include shortening of the tibia and a smaller calf circumference and smaller foot relative to the contralateral side. Frequently there is a dimple at the apex of the deformity. Radiographic examination of the entire extremity from hip to ankle should be performed. Radiographs demonstrate the degree of bowing and in some cases thickening and sclerosis of the diaphyseal cortices on the compression side of the deformity with obliteration of the intramedullary canal. There is no increased fracture risk associated with the deformity.

Posteromedial bowing tends to resolve with growth, such that much of the deformity resolves by 2 years of age, with continued gradual correction beyond that. The shortening of the tibia and fibula persists, however, and progressively worsens during growth. Leg length inequality at skeletal maturity averages 4.1 cm (Hofmann and Wenger, 1981). Early referral to and serial follow-up assessments by a pediatric orthopedist are necessary to appropriately time epiphyseodesis surgery of the normal longer leg to allow equal leg lengths at skeletal maturity.

The second and most serious type of tibial bowing is anterolateral. It is usually identified at the newborn examination. It is unilateral and most frequently associated with congenital pseudoarthrosis of

the tibia. Although its cause is unknown, congenital pseudoarthrosis of the tibia is associated with neurofibromatosis type 1 (NF1) in 40%–80% of cases (Masserman et al., 1974; Paterson, 1989; Thompson, 2001). It is arguably the most challenging congenital malformation to treat in orthopedics. It is estimated to occur in 1 in 140,000 live births (Crawford and Schorry, 1999). Cutaneous signs of NF1 may be evident. If they are not, NF1 should remain a consideration as cutaneous and ocular manifestations may not be present in the newborn, and thus the child should be followed up expectantly.

If fracture has occurred, motion at the pseudoarthrosis site will be apparent. The foot may be normal or slightly small. The ankle may be in slight valgus to compensate for the bowing. The natural history of congenital pseudoarthrosis of the tibia is that of fracture with nonunion and repeated surgical attempts at obtaining union. Most of these attempts fail; if one such procedure succeeds, however, repeated fracture is likely, and the cycle begins again. Frequently, amputation is the end result. Because of this possibility, efforts are best directed at prevention of initial fracture.

Orthopedic consultation for anterolateral tibial bowing is imperative. In the perambulatory child, a total-contact (clamshell) ankle-foot orthosis should be fabricated and worn at all times except for bathing, to diminish the chance of fracture. When the child begins to walk, the orthosis may be extended above the knee with a drop-lock hinge to allow sitting. Bracing is continued until skeletal maturity is attained. Although definite proof that long-term bracing affects the natural history of this condition is lacking, most orthopedists consider that bracing is warranted. Under no circumstances should an osteotomy to correct the bowing of an unfractured tibia be undertaken because development of a pseudoarthrosis is likely to result. Many treatment options exist once a documented pseudoarthrosis occurs. Long-term immobilization, external fixation, internal fixation, bone transport, bone grafting, microvascular bone transfer, and electric stimulation have been attempted (Crawford and Schorry, 1999). High failure rates are commonly reported. Amputation has been advocated as a salvage procedure after failed attempts at union and typically has good outcomes (Jacobsen et al., 1983). Herring et al. (1986) reported that children who underwent Syme amputation had better psychologic and orthopedic functioning than those children who underwent numerous corrective surgical procedures.

Tibial bowing in the anteromedial direction can occur and is typically seen in children with fibular hemimelia, a condition with multiple lower limb anomalies. In addition to a deficient or absent fibula, there is a strong association with absent lateral rays of the foot, a bowed tibia, knee deformities, a short femur, hip dysplasia, and leg length discrepancy. Management might include deformity correction, limb lengthening, and foot, knee, or hip reconstruction.

Tibial bowing may also be confused with a congenital knee dislocation. This is a rare condition, noted at birth, with a reported incidence of 0.017 per 1000 (Jacobsen and Vopalecky, 1985). The cause is unknown. It is most likely related to contracture of the quadriceps muscle. Congenital knee dislocations are associated with clubfoot, arthrogryposis, myelodysplasia, and Larsen syndrome, with ipsilateral hip dislocation occurring in 70%–100% of cases (Curtis and Fisher, 1969). The knee can be hyperextended so severely that the foot might even reach the child's face, and the knee cannot be flexed. Nonsurgical treatment, consisting of manipulation and serial casting, should be started promptly after radiographic diagnosis and before management of the dislocated or dysplastic hip. Surgery is reserved for children who do not respond to nonsurgical treatment

and is best performed at the age of approximately 6 months (Nogi and MacEwen, 1982; Fig. 101.9).

Congenital Vertebral Malformations

Congenital vertebral malformations occur in 0.5 in 1000 to 1 in 1000 live births. Although a minority of cases may be due to genetic inheritance, there are no established gene defects that solely account for these disorders. The syndromes associated with them include Klippel–Feil syndrome, Goldenhar syndrome, and VATER (VACTERL) sequence. Likewise, many congenital vertebral malformations occur in isolation and may be due to intrauterine exposures such as exposure to high levels of blood glucose (hyperglycemia), exposure to carbon monoxide, or exposure to antiepileptic drugs. The ultimate concern with congenital vertebral anomalies is their potential to result in significant spinal deformity; namely, scoliosis or kyphosis or a combination of the two. Many, however, remain asymptomatic throughout life.

Defects can be attributed to a failure of formation, a failure of segmentation, or both. Failures of formation result from asymmetric vertebral body formation and ensuing development of a hemivertebra. Hemivertebrae can be incomplete, with partial retention of the affected side, or complete. When partial retention of the pedicle occurs, a wedge vertebra develops. Complete hemivertebra can be

further categorized. Radiographically, the presence of open disk spaces signifies the presence of growth plates and therefore growth potential. Unsegmented hemivertebrae, in which the segment is fused to one vertebra or both adjacent vertebrae, have less growth potential and therefore less deformity potential. Fully segmented hemivertebrae retain full growth potential from both the cranial end and the caudal end and consequently demonstrate a much greater propensity to result in significant deformity. Failures of segmentation are characterized by bony fusions (bars) between adjacent vertebrae. Bilateral bars result in “block vertebrae” that, because of their symmetry, have minimal potential for deformity.

The propensity to result in a clinically significant deformity depends on the location of the defect, the type of defect, and the age of the patient (Hedequist and Emans, 2007). Curves at the lumbosacral and cervicothoracic junctions may result in more clinically apparent deformities. Prediction of progression is largely driven by the presence of unbalanced defects (McMaster and Ohtsuka, 1982). In order of severity, the risk of progression in congenital spinal deformities is associated with the following defects: unilateral bar with contralateral hemivertebra, unilateral bar, hemivertebra, wedge vertebra, and block vertebra (Fig. 101.10). Additionally, the presence of multiple anomalies at multiple levels (e.g., multiple hemivertebra) can result in additional risk of progression when they are on the ipsilateral side or, conversely, may result in balanced growth when they are on contralateral sides of the spine.

All patients with known congenital spinal deformities should be evaluated for associated cardiac and renal anomalies. Cardiac anomalies are found in approximately 15% of these children and are usually evident on physical examination. Routine screening with an echocardiogram is not recommended unless clinical findings are suggestive (Prybis et al., 2007). Renal anomalies, on the other hand, are often clinically silent and have been reported in up to 37% of children with known congenital spinal anomalies (Riccio et al., 2007). Thus routine sonography of the urinary tract system is recommended for all children with congenital spinal malformations.

Occult intraspinal anomalies are found in up to 30% of children with congenital spinal malformations. These include Chiari malformations, syringomyelia, tethered cord, reduced spinal cord diameter, and diastematomyelia. Associated physical examination findings are those consistent with occult dysraphism, such as dimpling of the skin, pigmentation changes, or the presence of hairy patches or skin tags in the lower back or intergluteal cleft. Changes to the lower extremities such as atrophy, foot deformities,

and asymmetric or pathologic reflexes are also suggestive of intraspinal defects.

Infants with congenital spine anomalies should initially be evaluated with dedicated plain radiographs of the whole spine. Coned-down views of affected parts of the spine may offer additional information about the anatomy of interest. Rib anomalies should be noted, because they are commonly associated with thoracic spine malformations and may have significant long-term implications with regard to restrictive lung disease (Campbell and Hell-Vocke, 2003). The position of the scapula should also be evaluated, because Sprengel deformity is found in up to 50% of children with congenital cervical spine anomalies (Hensinger et al., 1974). The use of magnetic resonance imaging (MRI) is reserved for those children preparing to undergo surgical intervention or those with clinical evidence of neurologic abnormality (Hedequist and Emans, 2007). Cutaneous anomalies of the lumbar spine in the newborn may be evaluated by ultrasonography. This is a particularly effective method for determining the level of the conus medullaris and thus the presence of tethered cord. Computed tomography is typically not indicated in the newborn owing to concerns of unneeded radiation exposure, but if done for other reasons, it can give additional detail on spinal anatomy.

Obstetric Trauma

Birth trauma can be divided into two categories: fractures and neurologic injuries. Birth fractures most commonly involve the clavicle, with clavicular fractures occurring in 2 per 1000 to 35 per 1000 vaginal births (Sanford, 1931; Farkas and Levine, 1950; Cohen and Otto, 1980; Kaplan et al., 1998). Birth fractures also occur in the proximal part of the humerus (Broker and Burbach, 1990; Fisher et al., 1995), the femur (0.13 per 1000 births) (Morris et al., 2002), and even the thoracic spine. It is important to note that clavicular fracture can be seen in combination with a proximal humeral physal separation or in combination with a brachial plexus injury. Reported risk factors for upper extremity birth fractures include large size of the baby, limited experience of the obstetrician, and a midforceps delivery (Cohen and Otto, 1980). Risk factors for femoral fracture include twin gestation, breech presentation, prematurity, and osteoporosis (Morris et al., 2002). Nadas et al. (1993) have reported an association of long-bone fractures with cesarean delivery, breech delivery with assistance, and low birth weight.

The natural history of isolated birth fractures to the extremities is that of uneventful rapid healing without untoward sequelae. Clavicle fractures may be difficult to diagnose, because the neonate may be asymptomatic. In a study of 300 newborns, radiographs revealed five unsuspected clavicle fractures (Farkas and Levine, 1950). Newborns with either a clavicle fracture or a proximal humeral physal separation often have pseudoparalysis of the upper extremity. Considerations in the differential diagnosis include an obstetric brachial plexus palsy and hematogenous metaphyseal osteomyelitis of the humerus with septic glenohumeral arthritis. Pain with direct palpation of the clavicle may be present with obvious deformity. Pain with motion of the shoulder joint and with palpation of the proximal part of the humerus may be caused by either fracture or infection. Elicitation of neonatal reflexes such as the Moro reflex and asymmetric tonic neck reflex (ATNR) may be helpful in evaluating active upper extremity muscle function (Sanford, 1931). Radiographs should be obtained. Ultrasound evaluation of the proximal part of the humerus may be helpful because the proximal humeral epiphysis is entirely cartilaginous at

birth and therefore radiolucent. Ultrasound examination can detect proximal physal separation, metaphyseal osteomyelitis, and septic shoulder arthritis (Broker and Burbach, 1990; Fisher et al., 1995).

Asymptomatic birth fractures of the clavicle and humerus in neonates can be observed. The fracture will unite in short order, with remodeling of bone occurring with growth. Symptomatic fractures in which the child exhibits pseudoparalysis of the upper extremity should be treated with 7 to 10 days of immobilization in a soft dressing or until symptoms subside. Femoral birth fractures can be treated with a Pavlik harness with good results (Morris et al., 2002). This device provides a simple means of immobilization that is accepted well by new parents. Excellent outcomes with no residual deformities or limb length inequalities can be expected.

The presence of multiple long-bone and rib fractures at birth may herald the presence of OI. Prenatal diagnosis is commonly made by ultrasonographic screening, as early as 13 to 14 weeks' gestation, on the basis of deformity (Cheung and Glorieux, 2008). OI is typically classified by the Sillence classification, with type II and type III being the most common types identified in the perinatal period (Sillence et al., 1979). Type II OI is lethal in the neonatal period, whereas most children with type III OI survive into adulthood with considerable short stature and fracture-related morbidity. Thus prompt genetic consultation is critical to establish a diagnosis and prognosis for an affected child. A diagnosis of Bruck syndrome should be considered when clinical and radiographic findings of OI are coupled with joint contractures (Schwarze et al., 2013). Infants with type III OI often require substantial respiratory support and pain management because of rib fractures, with respiratory failure being identified as the most common cause of death in the neonatal period. Treatment of long fractures is primarily to support pain management and can be achieved by custom splints or merely soft supports, such as pillows or blankets. Patients with multiple fractures at birth who are expected to survive the neonatal period should be considered for bisphosphonate treatment (Shapiro and Sponseller, 2009).

Brachial plexus injuries represent the second category of birth trauma afflicting newborns. The mechanism of injury is a separation of the head from the shoulder by lateral bending of the neck with simultaneous shoulder depression during vaginal delivery resulting in a stretching of the brachial plexus. These injuries occur in 1 per 1000 to 4 per 1000 live births (Hardy, 1981; Greenwald et al., 1984). Risk factors include maternal diabetes, large birthweight, prolonged labor, forceps delivery, and shoulder dystocia during a vertex delivery (Piatt, 2004). They are rarely seen in cesarean deliveries. Brachial plexus palsies are associated with clavicle and humerus fractures, as well as torticollis.

The brachial plexus receives contributions from the anterior spinal nerve roots of C5 through T1, which combine and divide to form the peripheral nerves that supply the motor innervation to the upper extremity. Three major injuries are encountered. The most frequent injury is to the upper trunk that involves the C5 and C6 nerve roots primarily and results in an Erb palsy. Affected infants lack external rotation and abduction of the shoulder. Hand function is preserved. The next most frequently occurring injury is a global plexus palsy involving the C5 through T1 nerve roots. This results in flaccid paralysis of the involved upper extremity, including the hand. An isolated lower plexus injury involving the C8 and T1 nerve roots, termed *Klumpke palsy*, is the least common and may be a manifestation of a recovered global plexus injury (Waters, 1997).

The physical examination has proved to be the most reliable method of assessing the level and severity of the neural injury and

thereby predicting the potential for spontaneous recovery (Waters, 1997; Noetzel et al., 2001). Myelography, computed tomographic myelography, magnetic resonance imaging, and electrodiagnostic studies have not proved useful in predicting recovery (Waters, 1997). Active shoulder, elbow, wrist, and finger motion need to be assessed (Piatt, 2004). Frequently, such assessment can be facilitated by elicitation of the primitive reflexes that are transiently present in normal newborns. The hand grasp reflex is normal in all newborns and disappears between 2 and 4 months. The examiner's little finger is placed on the ulnar aspect of the infant's palm, and the infant's fingers reflexively flex and grasp the examiner's finger. The Moro reflex begins to fade at 3 months of age. It is elicited by the examiner holding the newborn's hands while raising the baby off the table and then suddenly releasing them. In response, the newborn extends the spine, abducts and extends all four limbs and digits, and then subsequently adducts and flexes the limbs and digits. Last, the ATNR, or fencing reflex, can be elicited in a normal newborn until the age of 4 months. With the infant lying supine on an examining table, the head is rotated to one side by the examiner. The infant should respond by extending the elbow on the side toward which the face is looking and by flexing the opposite elbow. In newborns with a brachial plexus injury, some of these reflexes will be abnormal because of lack of motor control. For instance, the newborn with an Erb palsy will, most notably, not be able to actively flex at the elbow during the ATNR or the Moro reflex. The presence or absence of Horner syndrome (contracted pupil, drooping eyelid, and decreased sweating on the affected side) must also be noted.

An affected infant needs repeated serial examinations until 6 months of age. Return of biceps function by 3 months is the most important indicator of brachial plexus recovery (Michelow et al., 1994). When biceps recovery is combined with the return of shoulder abduction, wrist extension, and finger extension, there is a 95% chance of normal function (Michelow et al., 1994). When biceps function recovers later than 3 months, it is rare for the child to have complete recovery of normal function (Waters, 1999). A total plexus palsy or the presence of Horner syndrome also heralds a poor prognosis (Michelow et al., 1994; Waters, 1997).

The initial treatment of obstetric brachial plexus injury is aimed at avoiding contractures of the shoulder, elbow, forearm, and hand with occupational or physical therapy during the observation-for-recovery phase. Fortunately, as few as 1 in 10 infants with brachial plexus palsies at birth will require surgical intervention (Piatt, 2004). With the decision for surgery being based on muscle function recovery, prompt referral to a specialist is recommended to initiate monthly neurologic examinations.

Brachial plexus exploration with subsequent reconstruction is indicated for infants with total plexus involvement, Horner syndrome, and no return of biceps function at 3 months and for infants with a C5 to C6 (Erb) plexopathy and no return of biceps function at 3 to 6 months (Waters, 1997). Surgery is undertaken between 3 and 6 months of age. Using this algorithm prospectively, Waters (1999) operated on six infants at 6 months and found that their results were better than those for the 15 patients with biceps recovery at 5 months but worse than those for the 11 patients with biceps recovery at 4 months. Despite treatment as outlined, some children will have residual deficits. Secondary reconstruction, for chronic brachial plexopathy resulting in a dysfunctional shoulder, can be achieved with a tendon transfer of the latissimus dorsi and teres major to the rotator cuff or by derotational osteotomy of the humerus. These procedures and others designed to correct limitations in hand and forearm function are undertaken after the true scope

of the disability has been assessed. A more recent study suggested that some infants with no biceps recovery by 3 months will eventually achieve adequate biceps and shoulder function without surgery (Smith et al., 2004). The optimal timing of surgical intervention remains controversial. Surgical exploration after 18 months is of little benefit.

Neonatal Osteomyelitis and Septic Arthritis

Osteomyelitis is a bacterial infection of bone, and septic arthritis is a pyogenic infection of a joint. Incidence rates of 0.12 per 1000 live births and 0.67 per 1000 neonatal intensive care unit admissions (Ho et al., 1989) have been reported for septic arthritis. The mortality rate is reported to be 7.3% (Caksen et al., 2000). The hip, knee, and shoulder joints are involved most frequently. Neonates are particularly susceptible to osteomyelitis and septic arthritis because of an immature immune response, resulting in vulnerability to organisms that are not ordinarily virulent in infants and children, and because of delays in expressing the classic physical findings associated with these conditions (Morrissy, 2001).

Two subgroups of neonates are affected: premature neonates requiring prolonged hospitalization and otherwise healthy newborns in whom presentation occurs within 2 to 4 weeks after delivery (Morrissy, 2001). Most cases of neonatal osteomyelitis and septic arthritis result from hematogenous spread, but some occur from direct inoculation during percutaneous arterial blood sampling (especially if obtained from the femoral artery). Acute hematogenous osteomyelitis (AHO) and septic arthritis in hospitalized neonates usually occur in premature infants with multiple peripheral and central vascular catheters (Laborada et al., 2003). These infections are frequently caused by *Staphylococcus aureus* or gram-negative organisms (Deshpande et al., 2004). Up to 40% of these patients may demonstrate multiple areas of involvement, characterized by swelling and tenderness, and are systemically ill (Fox and Sprunt, 1978; Bergdahl et al., 1985).

This presentation contrasts with that of the typical out-of-hospital newborn with AHO and septic arthritis, in whom 2 to 4 weeks after birth swelling, pseudoparalysis (lack of active movement of affected limb) and tenderness of the extremity present and who feeds well and is not systemically ill (Morrissy, 2001). *S. aureus* and group B streptococcus are the most common organisms encountered in this latter population. Because of the immature immune response, neonates frequently do not demonstrate fever, leukocytosis, or elevation in erythrocyte sedimentation rates (Scott et al., 1990). However, C-reactive protein is a reliable indicator of AHO and septic arthritis, with a negative predictive value of 95% (Laborada et al., 2003). Blood culture findings are positive in only 50% of patients; cultures of synovial aspirates identify an organism in only 30% of cases (Lyon and Evanich, 1999).

Imaging studies are critical in diagnosing neonatal osteomyelitis and septic arthritis. Plain radiographs are usually the first study performed although they do not always yield a diagnosis in early infections. X-rays demonstrate soft tissue swelling by 3 days, but bone changes are not present for 1 week after the onset of symptoms (Jackson and Nelson, 1982; Dormans and Drummond, 1994). Ultrasound examination is our preferred radiologic method for evaluating the neonate with suspected AHO and/or septic arthritis, as it detects joint effusions and subperiosteal and soft tissue fluid collections and can guide aspiration. If an infection is still suspected despite negative findings after radiographic and ultrasound examination, nuclear scintigraphy and MRI are considered. Both are highly sensitive but may require that the infant be sedated. Scintigraphy

• **Fig. 101.11** Unrecognized neonatal hip sepsis can result in complete dissolution of the femoral head as demonstrated in this child's left hip radiograph.

is particularly useful in identifying multifocal involvement, which is an important consideration in neonatal osteomyelitis. MRI provides accurate regional information on both the soft tissues and bones and is highly sensitive in identifying early infections (Kothari et al., 2001).

In neonates, and before the appearance of the secondary ossification center, the epiphysis receives blood directly from metaphyseal blood vessels. When the infection occurs in these metaphyseal veins causing osteomyelitis, it can traverse the growth plate into the epiphysis, cause abscess formation, and rupture into the joint (Ogden, 1979). Thus septic arthritis is a sequela of adjacent osteomyelitis in up to 76% of neonates (Fox and Sprunt, 1978; Bergdahl et al., 1985). The hip and shoulder are two of the more common sites of neonatal septic arthritis as they have intra-articular metaphyses, allowing a subperiosteal route of decompression for pus into the joint. Because of this unique ability to spread from the metaphysis through the growth plate into the joint, early detection and treatment are necessary to avoid permanent damage to each of these structures. Infection can result in destruction of the growth plate and articular cartilage in short order, resulting in growth disturbances and precocious arthritis. When an area of involvement is suspected, aspiration should be undertaken (Morrissey,

2001). This may confirm the diagnosis and provide fluid for Gram stain and culture so as to better direct treatment. Osteomyelitis without a pus collection in bone or soft tissue can typically be managed with antibiotic therapy; septic arthritis and subperiosteal and bone abscesses should always be debrided surgically in the operating room (Fig. 101.11).

Skeletal Dysplasias and Heritable Connective Tissue Disorders

GEORGE E. TILLER AND GARY A. BELLUS

KEY POINTS

- Many skeletal dysplasias as well as many connective tissue disorders look similar in the newborn period, especially in premature infants. Arriving at the most accurate diagnosis possible is essential to proper medical decision making and counseling the family. Utilizing all resources available (medical consultants, texts, online resources, and molecular diagnostics) contributes to this process.
- With respect to molecular diagnostics, (1) it is not essential in all cases, especially where diagnoses can be made clinically by physical examination and/or radiographs, (2) particular mutations within a gene do not always determine prognosis, with notable exceptions (i.e., *FGFR3*, *COL1A1*), (3) diagnostic molecular testing is commercially available in all disorders for which a gene has been identified, and prenatal diagnosis is available if the particular gene mutation has been previously identified in an affected individual, and (4) medical geneticists and genetics laboratory directors can aid in choosing the best approach to a molecular diagnosis (which may take several weeks to complete), so as to accommodate disorders exhibiting genetic heterogeneity.
- As in all cases, the family should be kept updated on current clinical status, what is known, what remains unknown, and the timeline for receiving additional diagnostic and prognostic input.

The skeletal dysplasias, or osteochondrodysplasias, are disorders of the development and growth of cartilage and bone. The connective tissue disorders involve abnormalities of the cells' supporting and connecting structures in the matrix. In one series of 126,316 deliveries monitored for 15 years, the incidence of skeletal dysplasias was 2.14 in 10,000 ([Rasmussen et al., 1996](#)). With the growing use and accuracy of ultrasonography for prenatal care, a greater number of osteochondrodysplasias and connective tissue disorders are diagnosed prenatally.

The most recent classification of skeletal dysplasias into 42 groups is based on radiologic, clinical, and/or molecular criteria ([Bonafé et al., 2015](#)). This chapter focuses on several of the more "common" skeletal dysplasias (see [Tables 102.1](#) and [102.2](#) for an expanded list) and connective tissue disorders ([Table 102.3](#)) that manifest themselves prenatally or perinatally, but the discussion is not exhaustive. The osteochondrodysplasias have been reviewed extensively elsewhere ([Krakow and Rimoin, 2010](#); [Krakow, 2015](#)).

There are many different connective tissue molecules, including collagens (more than 24 types), elastin, fibrillin (two types), and

microfibril-associated glycoproteins. These molecules are components of tissues such as bone, cartilage, skin, vascular media, tendon, ligament, and basement membrane in many organs. The heritable disorders of connective tissue are varied, may be very dissimilar clinically, and may manifest themselves in utero or at any age postnatally. Those that may manifest themselves at birth include the early-onset (neonatal) form of Marfan syndrome, congenital contractural arachnodactyly (CCA; Beals syndrome), cutis laxa, some forms of Ehlers–Danlos syndrome (EDS), and Menkes disease.

Clinical Spectra of Disorders With Common Molecular Bases

The number of clinically distinguishable skeletal dysplasias and connective tissue disorders is extensive. With advances in molecular knowledge, several different dysplasias have been recognized to have mutations in the same genes. In some of these disorders, clinical similarities noted previously suggested a common cause. One such clinical spectrum includes achondroplasia, hypochondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), and thanatophoric dysplasia, all of which are caused by mutations in the fibroblast growth factor receptor 3 gene (*FGFR3*; [Shiang et al., 1994](#); [Bellus et al., 1995](#); [Wilcox et al., 1998](#); [Vajo et al., 2000](#)). Another spectrum of disorders includes Stickler syndrome, Kniest dysplasia, some forms of spondyloepimetaphyseal dysplasia, spondyloepiphyseal dysplasia congenita (SEDC), hypochondrogenesis, achondrogenesis type II, and recessive multiple epiphyseal dysplasia, all of which are caused by mutations in the gene for collagen type II, *COL2A1* ([Spranger et al., 1994](#)). With other disorders, the common cause is not as obvious clinically: diastrophic dysplasia, atelosteogenesis type II, and achondrogenesis type IB are all caused by mutations in the *SLC26A2* gene ([Hastbacka et al., 1994, 1996](#); [Superti-Furga et al., 1996](#); [Bonafé et al., 2013b](#)). The obverse is also evident, wherein a specific clinical entity (e.g., multiple epiphyseal dysplasia) may be caused by a mutation in one of several genes—a concept known as *genetic heterogeneity*.

Approach to Diagnosis

An early and precise diagnosis is important for prognosis, optimal immediate-term and long-term management, accurate genetic

**TABLE
102.1****Lethal Skeletal Dysplasias Manifesting Themselves Prenatally or Perinatally**

| Dysplasia | Skeletal Features | Nonskeletal Features | Radiographic Features | Inheritance and Genes |
|--|--|---|--|---|
| Achondrogenesis type IB (OMIM 600972) | Soft cranium; short, round chest; very short limbs | Round face; polyhydramnios | Poorly ossified calvarium; short ribs with fractures and beading; nonossified vertebrae; short broad femurs with metaphyseal spikes, short broad tibiae and fibulae | AR; <i>SLC26A2</i> |
| Achondrogenesis type II, hypochondrogenesis (OMIM 200610) | Large head, flat face, cleft palate; short trunk; very short limbs (micromelia) | Fetal hydrops; distended abdomen | Lack of vertebral mineralization; short limbs (all segments); enlarged cranium with normal ossification | AD; <i>COL2A1</i> |
| Asphyxiating thoracic dystrophy (Jeune syndrome) (OMIM 263510) | Narrow, long chest; variable limb shortening | Lethal pulmonary insufficiency | Very short ribs with anterior cupping; short limbs with wide proximal femoral metaphyses; premature ossification of proximal femoral epiphysis | AR; <i>DYNC2H1</i> , <i>IFT80</i> , <i>IFT140</i> , <i>IFT172</i> , <i>WDR19</i> , <i>WDR34</i> , <i>TTC21B</i> |
| Atelosteogenesis type II (OMIM 256050) | Narrow chest, short limbs, joint dislocations, equinovarus deformities, gap between first and second digits | Cleft palate, laryngeal stenosis; patent foramen ovale | Occasional coronal and sagittal vertebral clefts; short ribs; short “dumbbell” humeri and femurs, small fibulae; large second and third metacarpals; small round midphalanges | AR; <i>SLC26A2</i> |
| Campomelic dysplasia (OMIM 114290) | Large cranium; small face, flat nasal bridge, cleft soft palate; small, narrow chest; angulated thighs and legs; dimples on legs | Polyhydramnios, congenital cardiac abnormalities; female external genitalia in XY males | Large dolichocephalic calvarium with shallow orbits; short and wavy ribs, often 11 pairs; hypoplastic scapula; small, flat vertebrae; tall, narrow pelvis; relatively long, thin limbs with bent femurs and short tibiae | AD (most are new mutations); <i>SOX9</i> |
| Chondrodysplasia punctata, rhizomelic type 1 (OMIM 215100) | Flat face; very flat nasal bridge and tip; proximal shortening of limbs | Cataracts; joint contractures; ichthyosiform erythroderma | Wide coronal vertebral clefts; short humeri and femurs; stippled epiphyses of long bones, pelvis and periarticular areas; trapezoid ilia | AR; <i>PEX7</i> |
| Short-rib polydactyly types I and III (OMIM 208500 and 613091) | Hydropic appearance, round flat face, micrognathia, very narrow chest, very short limbs, postaxial polydactyly | Cardiac, renal, and/or anal malformations | Normal calvarium; very short, horizontal ribs; flat, wide intervertebral disk spaces; small pelvis; short limbs with lateral and medial metaphyseal spurs | AR; <i>DYNC2H1</i> (for type III only), <i>IFT80</i> , <i>WDR34</i> |
| Thanatophoric dysplasia (OMIM 187600) | Large cranium, proptosis, flat nasal bridge, narrow chest, very short limbs (all segments) | Polyhydramnios, hydrocephalus, brain anomalies, congenital cardiac abnormalities | Large calvarium, small foramen magnum, cloverleaf skull (type 2); short, splayed, cupped ribs; very flat U-shaped vertebrae; short, flat pelvis; short, bowed limbs; metaphyseal flare with spike | AD (most are new mutations); <i>FGFR3</i> |

AD, Autosomal dominant; AR, autosomal recessive; OMIM, online mendelian inheritance in man.

counseling about recurrence risk, and identification of other possibly affected family members or disease carriers. An example is the group of disorders with punctate calcifications (“stippling”) in epiphyses, called *chondrodysplasia punctata*. There are several types, with three possible modes of inheritance: autosomal recessive, X-linked recessive, and X-linked dominant (see Table 102.1). As in any uncommon genetic condition, multiple components may be required to arrive at the correct diagnosis: a complete physical examination, three-generation family history, radiologic studies, and biochemical and/or molecular tests.

Most skeletal dysplasias cause short stature, which can be proportionate or disproportionate. The disproportion may be evident as a short-limbed or short-trunk form of dwarfism. If the limbs

are affected, there may be segmental shortening of the upper arms and thighs (rhizomelia), forearms and legs (mesomelia), or hands and feet (acromelia). Most skeletal dysplasias that manifest themselves at birth involve short limbs. Accurate measurements of length (on a firm surface) and head and chest circumferences must be plotted on standard growth curves, with measurement of arm span and calculation of upper body/lower body segment ratios to objectively assess disproportion.

Other skeletal characteristics can give important clues for specific disorders:

- Children with achondroplasia and thanatophoric dysplasia have large heads (macrocephaly). Cloverleaf skull deformity is present in some forms of thanatophoric dysplasias.

TABLE 102.2**Nonlethal Skeletal Dysplasias Manifesting Themselves Prenatally or Perinatally**

| Dysplasia | Skeletal Features | Nonskeletal Features | Radiographic Features | Inheritance and Gene |
|--|---|--|---|---|
| Achondroplasia (OMIM 100800) | Large cranium; frontal bossing, flat nasal bridge, short neck; slightly narrow chest; proximal limb shortening (rhizomelia), short trident hands; brachydactyly; joint laxity | Hypotonia: delayed motor milestones; spinal stenosis causing spinal compression; small foramen magnum may cause hydrocephalus and/or apnea | Large calvarium, small foramen magnum; diminished lumbosacral interpedicular space, short pedicles; short ribs with anterior cupping; short humeri and femurs; relatively long fibulas; metaphyseal flare; small iliac wings | AD (most are new mutations); <i>FGFR3</i> |
| Chondrodysplasia punctata, X-linked recessive (OMIM 302950) | Distal phalangeal hypoplasia; severe hypoplasia of nose; short stature | Cataracts; hearing loss; congenital ichthyosis; anosmia and hypogonadism (in contiguous gene deletion patients) | Distal phalangeal hypoplasia; stippled epiphyses of long bones; paravertebral stippling | XLR; <i>ARSE</i> |
| Chondrodysplasia punctata, X-linked dominant (Conradi–Hünemann syndrome) (OMIM 302960) | Asymmetric rhizomesomelia | Congenital cataracts; ichthyosis; patchy alopecia | Stippled epiphyses of long bones; paravertebral stippling; tracheal calcifications | XLD; <i>EBP</i> |
| Diastrophic dysplasia (OMIM 222600) | Cleft palate; micrognathia; normal chest at birth; very short limbs; thumbs proximally placed and adducted (hitchhiker thumb); equinovarus; limited joint movement | Cystic masses in auricles (cauliflower ears) during infancy; deafness caused by lack or fusion of ossicles; narrow external auditory canal | Premature ossification of rib cartilage; narrow L1–L5 interpedicular spaces; scoliosis; short limbs; short ulnae and fibulae (mesomelia); broad flared metaphyses; ovoid first metacarpals; variable symphalangism of proximal interphalangeal joints | AR; <i>SLC26A2</i> |
| Kniest syndrome (OMIM 156550) | Large cranium; flat face with large eyes, flat nasal bridge, cleft palate; proximal limb shortening, enlarged joints, flexion contractures | Infancy: tracheomalacia Childhood: myopia and retinal detachment, hearing loss, delayed motor development | Frontal and maxillary hypoplasia, shallow orbits; slightly short ribs; flat vertebrae with coronal clefts; irregular acetabular roof; short limbs with dumbbell metaphyses lateral bowing of femurs and tibiae | AD; <i>COL2A1</i> |
| Spondyloepiphyseal dysplasia congenita (OMIM 183900) | Flat face, cleft palate, short limbs | Infancy: tracheomalacia Childhood: myopia and retinal detachment, hearing loss | Frontal and maxillary hypoplasia, flat vertebrae, small pelvis with irregular acetabular roof, short limbs; normal hands and feet | AD; <i>COL2A1</i> |

AD, Autosomal dominant; AR, autosomal recessive; OMIM, online mendelian inheritance in man; XLD, X-linked dominant; XLR, X-linked recessive.

- A relatively long, narrow chest is seen in asphyxiating thoracic dystrophy.
- In achondroplasia, the hand is short and the fingers form a trident configuration. In diastrophic dysplasia, there are distinctive “hitchhiker” thumbs.
- Clubfeet may occur in diastrophic dysplasia, Kniest dysplasia, spondyloepiphyseal dysplasias, and osteogenesis imperfecta (OI) type II.
- Postaxial polydactyly occurs in short-rib polydactyly and asphyxiating thoracic and chondroectodermal dysplasias. Occasionally, preaxial polydactyly can also occur in the short-rib dysplasias.
- Multiple joint dislocations can manifest themselves at birth in Larsen syndrome, EDS type VII, atelosteogenesis, and Desbuquois syndrome.

The presence of extraskkeletal abnormalities may provide additional clues to diagnosis, as follows:

- Cleft palate may occur in campomelic, Kniest, spondyloepiphyseal, short-rib polydactyly (Majewski), atelosteogenesis type I and type II, hypochondrogenesis, and diastrophic dysplasias.
- Congenital cataracts are frequent in some forms of chondrodysplasia punctata.
- Congenital cardiac defects occur in short-rib polydactyly dysplasias and Ellis van Creveld syndrome.

Clinical and Molecular Evaluation

Radiographs of the entire skeleton, including the skull, thorax (with rib technique), long bones, hands, feet, pelvis, and lateral

**TABLE
102.3****Heritable Connective Tissue Disorders Manifesting Themselves Perinatally or in Childhood**

| Connective Tissue Disorders | Inheritance | Genes | Key Clinical Features |

spine, are essential for accurate diagnosis. Atlases dedicated to skeletal dysplasias are essential for this purpose (Lachman, 2006; Spranger et al., 2012), even for the experienced radiologist or neonatologist. Ultrasound images of the brain, heart, and kidneys may be helpful if anomalies in those organs are suspected. Detailed family history and measurements of family members may be helpful; disorders in more mildly affected members might have gone undiagnosed. Molecular investigations may be necessary to arrive at the proper diagnosis; given their complexity, such analyses should be considered after consultation with a clinical geneticist. The advent of “next-generation” DNA sequencing has led to more widespread availability of multi-gene diagnostic panels, which can be used when the diagnosis cannot be arrived at solely by clinical and radiographic means (see <https://www.genetests.org> or the Genetic Testing Registry at <https://www.ncbi.nlm.nih.gov/gtr/>). Molecular definition is

also helpful in the cases of autosomal recessive and X-linked disorders, as this information may be useful for counseling with respect to recurrence risk and prenatal diagnosis in subsequent pregnancies.

If the infant or fetus dies with the disorder undiagnosed, specimens of cartilage and skin fibroblasts should be obtained for histochemical tests, biochemical assays, and/or molecular analyses; these can be used to make or confirm diagnoses and permit accurate future prenatal diagnosis. Even if the molecular or enzymatic basis of the condition is not understood at the time, the tissue may be useful in the future. If photographs and skeletal radiographs were not obtained before death, they should be obtained after death. Additional information on clinical diagnosis may be obtained from the International Skeletal Dysplasia Registry at the University of California, Los Angeles (<http://ortho.ucla.edu/abouttheisdr>).

Disorders of Bone Fragility

Osteogenesis Imperfecta Types II and III

OI is characterized by increased bone fragility. There are classically four major clinical types: types II and III are the severest, manifesting themselves prenatally and perinatally (Steiner et al., 2013). However, fractures at birth can also occur in OI type I. Further heterogeneity in OI has recently been described.

Presentation

OI type II (perinatal lethal type) is estimated to affect 1 in 20,000 to 1 in 60,000 infants. Affected infants may be born prematurely, with low birthweight and disproportionately short stature. The limbs are short and bowed with extra circular skin creases; the hips are abducted and flexed. The head is soft and boggy, and minimal calvarial bone can be felt. The sclerae are dark blue, and the chest is narrow. The infant cries with handling because there may be many fractures at different stages of healing. Sixty percent of affected babies are stillborn or die during the first day of life, and 80% die by 1 month. With the growing use of ultrasonography, affected fetuses may be detected in the second trimester because of short and bowed or angulated limbs and narrow thoraces (Fig. 102.1).

OI type III (progressive deforming type) can manifest itself prenatally, perinatally, and in the first 2 years after birth. Prenatal and perinatal clinical features resemble those in OI type II but are less severe (Fig. 102.2), and perinatal death is not uncommon.

If not present at birth, fractures and deformations of the limbs develop in the first 2 years. The highest prevalence of fractures in OI, up to 200 in a lifetime, occur in type III. Extremely short stature, with an adult height of 92 to 108 cm, can result from microfractures in growth plates. The head may be large because the calvarium is soft with a large anterior fontanel. The sclerae may be blue initially but are white by puberty. The head assumes a triangular shape, with a bossed, broad forehead and a tapered, pointed chin. Later in childhood, dentinogenesis imperfecta and hearing loss may develop. Severe kyphoscoliosis may occur, leading to cardiopulmonary compromise, which is the major cause of early death.

Radiographic Features

Radiographs show the femurs in OI type II to be short, broad, and “telescoped” or “crumpled.” The tibiae are short and bowed or angulated, and the fibulae may be thin (see Fig. 102.1B). There is minimal to no calvarial mineralization. The acetabulae and iliac wings may be somewhat flattened. The ribs are short, wavy, and thin or broad, with “beading” from callus formation at fetal fracture sites.

In OI type III the femurs are short and deformed but not crumpled as in OI type II (see Fig. 102.2B–D). The other long bones are thinner than usual, with healing fractures incurred in utero, bowing, and deformations. The calvarium is undermineralized with a large anterior fontanel, and there are many wormian bones (small islands of bone in the suture spaces; see Fig. 102.2D). The ribs are thin and gracile.

• **Fig. 102.1** Osteogenesis Imperfecta Type II. (A) A 20-week fetus. The limbs are angulated and deformed from multiple fractures. (B) Radiograph of fetus (20 weeks' gestation) showing an absence of ossification in the calvarium, short telescoped or crumpled humeri and femurs, and short and wavy ribs with fractures.

• **Fig. 102.2** Osteogenesis Imperfecta Type III. (A) Neonate with normal face, short neck, and slightly short limbs. (B) Radiograph showing that the calvarium is undermineralized with wormian bones. (C) Radiograph showing the upper limbs, which have bowed humeri and callus in the ulnae. (D) Radiograph showing lower limbs with moderately short, thick femurs, and angulated tibiae and fibulae. (Courtesy of Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States.)

Etiology

OI is most commonly caused by mutations in one of the two genes encoding type I collagen (*COL1A1* and *COL1A2*), the predominant protein building block of bone. Clinically severe forms of OI are the result of qualitatively abnormal collagen synthesis rather than decreased production (Steiner et al., 2013), as well as the result of recessive disorders affecting noncollagen proteins (Forlino and Marini, 2016).

Inheritance

A fetus or infant with OI type II or III is usually the result of a spontaneous dominant-acting gene mutation, but there is a small risk of recurrence (approximately 6%) in subsequent siblings because of parental somatic or gonadal mosaicism. The parent is usually asymptomatic but may have minimal manifestations, such as short stature. Prenatal diagnosis is available if the particular gene mutation has been identified in the affected individual. Most cases of OI

are inherited as autosomal dominant traits, although rare recessive forms have been shown to be caused by mutations in genes encoding, for example, cartilage-associated protein (*CRTAP*; Barnes et al., 2006), prolyl 3-hydroxylase (*P3H1*), and cyclophylin B (*PPIB*; van Dijk et al., 2009).

Differential Diagnosis

Other lethal skeletal dysplasias may have abnormalities similar to those in OI type II and may be difficult to distinguish by prenatal ultrasonography; however, in experienced hands they can be differentiated on the basis of several ultrasound findings (Krakow et al., 2009). Krakow et al. (2008) published a retrospective analysis of 1500 prenatally diagnosed cases of skeletal dysplasias. The three most common prenatal-onset skeletal dysplasias were OI type II, thanatophoric dysplasia, and achondrogenesis type II, accounting for almost 40% of cases. Postnatal radiographs clearly reveal distinctive differences among thanatophoric dysplasia, campomelic dysplasia, achondrogenesis, and perinatal hypophosphatasia, among other disorders.

Management

If the diagnosis of OI is made prenatally, caesarean delivery has *not* been shown to decrease the fracture rate or increase the survival rate of severely affected fetuses (Cubert et al., 2001). Those severely affected with OI type II are not expected to survive the neonatal period. In OI type III the neonate needs careful handling to minimize pain and prevent further fractures. Analgesia alleviates pain. Consideration can be given to treatment with bisphosphonates (with use of intravenously administered pamidronate), which increase bone density, reduce the frequency of fractures and pain, possibly prevent short stature and deformations, and permit ambulation (Cheung and Glorieux, 2008). It is prudent to treat only severely affected children in whom the clinical benefits outweigh potential long-term effects.

Handling an Infant With Osteogenesis Imperfecta

When the diapers of an infant with OI are being changed, a hand should be placed behind the infant's buttocks with the forearm supporting the legs. Similarly, when the infant is lifted, the buttocks, head, and neck must be supported. The infant can be laid on a pillow to be carried. To transport the infant, an infant seat that reclines as much as possible and allows easy placement or removal should be used. The seat can be padded with egg crating or 1-inch foam. A layer of foam can be placed between the seat's harnesses and the child for extra protection. The car seat must always be placed in the back seat. Sling carriers and "umbrella" strollers should not be used for infants with OI because they do not give sufficient leg, head, and neck support.

Perinatal Hypophosphatasia

Presentation

Perinatal hypophosphatasia is a lethal condition characterized by short deformed limbs, a soft skull, blue sclerae, and under-mineralization of the entire skeleton, so many bones cannot be visualized and may seem absent in radiographs. In the skull, only the base can be visualized radiologically. There may be rachitic changes and fractures. Seizures that are responsive to pyridoxine may occur. There is polyhydramnios during pregnancy, and death can occur in utero. The disorder affects approximately 1 in 100,000 live births, and neonatal death is common (Mornet and Nunes, 2016).

Radiographic Features

The radiographic features of perinatal hypophosphatasia include polyhydramnios (prenatal); underossification, especially of the calvarium and long bones (with marked variability); small thoracic cavity; short, bowed limbs; spurs in the middle portion of the forearms and lower legs; and dense vertebral bodies.

Etiology

Mutations in the *ALPL* gene are responsible for deficiency of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP), thus causing perinatal hypophosphatasia. The serum alkaline phosphatase value is low. Serum values of inorganic pyrophosphate and pyridoxal 5'-phosphate (putative natural substrates for TNSALP) may be elevated, and urinary phosphoethanolamine level is elevated (Mornet and Nunes, 2016).

TNSALP acts on multiple substrates: the essential function of TNSALP is in osteoblastic bone matrix mineralization. TNSALP hydrolyzes inorganic pyrophosphate to phosphate, thought to be critical in promoting osteoblastic mineralization. If TNSALP is deficient, there is extracellular accumulation of inorganic pyrophosphate, which inhibits hydroxyapatite crystal formation and mineralization of the skeleton. TNSALP is also needed for delivery of pyridoxal 5'-phosphate into cells, where it is a cofactor (vitamin B6).

Inheritance

Perinatal hypophosphatasia is inherited as an autosomal recessive trait, with a 25% recurrence risk in future pregnancies. Prenatal diagnosis is optimized with the use of ultrasonography, assay of TNSALP activity in amniocytes, DNA mutation analysis if the previously affected infant's mutations were identified, or a combination of these methods.

Differential Diagnosis

Differential diagnoses include OI type II and achondrogenesis.

Management

Until very recently, treatment was primarily supportive and directed toward minimizing pain and discomfort. Clinical trials with a bone-targeted human recombinant enzyme replacement therapy have yielded promising results, and the drug has recently gained Food and Drug Administration approval (Whyte et al., 2016).

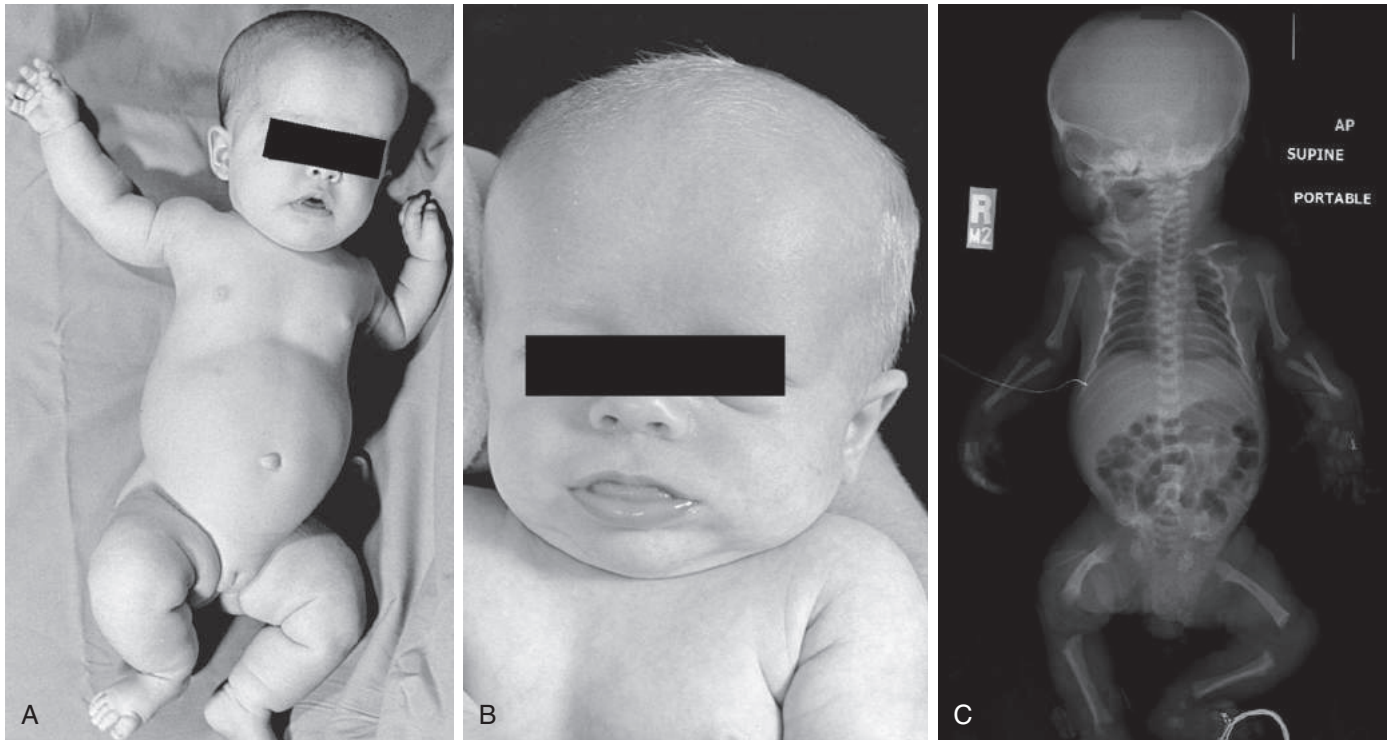

FGFR3 Spectrum

Achondroplasia

Presentation

Achondroplasia is the most common of the nonlethal chondrodysplasias; it affects 1 in 25,000 live births. It is characterized by short stature with short limbs, particularly rhizomelic (proximal) and acromelic (hands) shortening with trident hand configuration, large head with frontal prominence ("bossing"), flat nasal bridge and midface, long narrow trunk, joint laxity, and development of thoracolumbar kyphosis ("gibbus") in infancy (Fig. 102.3).

The foramen magnum and cervical spinal canal may be narrow and can cause compression of the spinal cord. Standards have been published for foramen magnum size in achondroplasia (Hecht et al., 1985). Compression of the lower brainstem and cervical spinal cord can lead to hypotonia, central apnea, retardation, quadriplegia, and (rarely) sudden death (Pauli et al., 1984, 1995). Perinatal or

• **Fig. 102.3** Achondroplasia. (A) Infant with achondroplasia who has macrocephaly and proximal limb shortening (rhizomelia). (B) Infant with achondroplasia who exhibits frontal bossing and flat nasal bridge. (C) Neonatal radiograph of achondroplasia illustrating a large skull, a somewhat narrow chest, short vertebral bodies with a lack of lumbar interpediculate flare, and rhizomelia. ([B] Courtesy Charles I. Scott, Nemours/Alfred I. du Pont Hospital for Children, Wilmington, Delaware, United States.)

infantile death can occur but is unusual (Simmons et al., 2014). Infants often sleep with their neck hyperextended, and symptoms can be exaggerated by neck flexion (Danielpour et al., 2007).

Radiographic Features

The calvarium is large with a relatively small foramen magnum and a short base. The lateral cerebral ventricles may be large, but hydrocephalus is not a common complication. The proximal long bones (humeri and femurs) are short, including the femoral neck. Fibulae are longer than tibiae. There is metaphyseal flaring. The hand is short with a trident configuration of the fingers, with short proximal and middle phalanges. Vertebrae are small and cuboid with short pedicles, and there may be anterior beaking of the first or second lumbar vertebrae; there is lack of widening of the interpedicular distance in the lumbar vertebrae. The pelvis has squared iliac wings (“elephant ear” appearance), a narrow greater sciatic notch, and flat acetabular roofs (see Fig. 102.3C). Compression of the cervical cord, if present, can be ascertained with magnetic resonance imaging cerebrospinal fluid flow studies in flexion and extension.

Etiology

The cause of achondroplasia is a mutation of the *FGFR3* gene, which encodes fibroblast growth factor receptor 3, a membrane-spanning tyrosine kinase receptor, which may form dimers with gene products of other gene family members: *FGFR1*, *FGFR2*, and *FGFR4*. The heterodimers serve as receptors for several fibroblast growth factors (Teven et al., 2014). More than 99% of individuals with achondroplasia have a mutation in the transmembrane domain of the *FGFR3* gene, in which arginine is substituted for glycine

(Gly380Arg; Shiang et al., 1994). The same gene is mutated at different sites in hypochondroplasia, thanatophoric dysplasia, SADDAN, Muenke craniosynostosis, and Crouzon craniosynostosis syndrome with acanthosis nigricans (Vajo et al., 2000). Histopathologic examination demonstrates a defect in the organization and maturation of the cartilage growth plates of long bones because of differing degrees of constitutive activation of the receptor.

Inheritance

The inheritance pattern in achondroplasia is autosomal dominant. Approximately 80% of cases are sporadic occurrences in a family, representing new mutations. Cases may be associated with advanced paternal age, and molecular studies have confirmed that new mutations are of paternal origin (Goriely and Wilkie, 2012). Rare recurrences due to gonadal mosaicism in a parent have been reported. Affected individuals are fertile, and achondroplasia is transmitted as a fully penetrant autosomal dominant trait, meaning that each person who inherits the mutant gene will manifest the condition.

Differential Diagnosis

Differential diagnoses include SADDAN (Vajo et al., 2000) and hypochondroplasia (Bellus et al., 1995).

Management

The infant with achondroplasia is often hypotonic; together with the large head, the hypotonia leads to delayed motor milestones. Development of thoracolumbar kyphosis may be exacerbated by unsupported sitting before truncal muscle strength is adequate; therefore infants should not be carried in flexed positions (including soft sling-carriers and umbrella strollers). Rear-facing car safety

seats should always be used. Most infants lose their kyphosis and develop lumbar lordosis when they begin walking.

Hydrocephalus may occasionally develop during the first 2 years, so the head circumference and body length should be carefully measured and plotted on standard achondroplasia growth charts (Trotter et al., 2005; Ireland et al., 2014). Routine imaging of the skull and brain is not recommended; however, development of hyperreflexia, hypotonia, or apnea may herald the development of clinically significant cord compression. Surgical decompression at the foramen magnum or the upper cervical spine may prevent neurologic damage, although most patients usually gain motor milestones late but spontaneously, because the foraminal diameter expands faster than the cord.

The upper airway in individuals with achondroplasia is small, often leading to obstructive apnea, snoring, and chronic serous otitis media beyond infancy. Treatment may consist of tonsillectomy, adenoidectomy, and placement of myringotomy tubes. Parents should be counseled about the clinical and hereditary aspects of the disorder and given a copy of the guidelines for health supervision of children with achondroplasia issued by the American Academy of Pediatrics (Trotter et al., 2005; Ireland et al., 2014).

Thanatophoric Dysplasia

Presentation

Thanatophoric dysplasia is one of the most common lethal dysplasias (Karczeski and Cutting, 2013), occurring in 1 in 45,000 births. It is characterized by extremely short limbs, long narrow trunk,

large head with bulging forehead, prominent eyes, flat nasal bridge, wide fontanel, and occasionally cloverleaf skull deformity (Fig. 102.4). It is differentiated into types I and II based on radiologic features and mutation specificity. Death typically occurs in the neonatal period from respiratory insufficiency, although rare survivors have been reported with multiple chronic problems. Polyhydramnios is common during pregnancy.

Radiographic Features

Femurs are short, flared at the metaphyses with a medial spike, and are bowed (type I) or straight (type II); other long bones are also short and bowed (see Fig. 102.4). The calvarium is large with a short base and small foramen magnum; cloverleaf skull is sometimes present in type I thanatophoric dysplasia and is severe in type II thanatophoric dysplasia. Vertebrae are strikingly flat (platyspondyly) with a U shape or an H shape in anteroposterior projection and uniform interpediculate narrowing. Ribs are short, cupped, and splayed anteriorly (Lachman, 2006).

Etiology

Thanatophoric dysplasia represents the severe end of the *FGFR3* spectrum. In thanatophoric dysplasia type I, the most common mutation in the extracellular domain is a substitution of cysteine for arginine at position 248 (Arg248Cys), but other mutations have been described throughout the gene. In all studied cases of thanatophoric dysplasia type II, there is a substitution of glutamate for lysine at position 650 (Lys650Glu; Karczeski and Cutting, 2013).

• **Fig. 102.4** Thanatophoric Dysplasia. (A) Stillborn with thanatophoric dysplasia with a large head with frontal bossing, narrow chest, short limbs, and short fingers (brachydactyly). (B) Radiograph of stillborn with thanatophoric dysplasia demonstrating large cranium, narrow chest, with short ribs, shortening of all long bones (micromelia) with bowing, flattened vertebral bodies (platyspondyly), and normal bone density. (C) Lateral spine radiograph of stillborn with thanatophoric dysplasia demonstrating remarkable platyspondyly.

Inheritance

All cases of thanatophoric dysplasia, as with most cases of achondroplasia and hypochondroplasia, occur sporadically and result from new autosomal dominant mutations. Nevertheless, there may be a small risk of recurrence to siblings of an infant with sporadic thanatophoric dysplasia, possibly caused by gonadal mosaicism. Prenatal diagnosis is available if the particular gene mutation has been previously identified in an affected individual.

Differential Diagnosis

Differential diagnoses include OI types II and III, achondroplasia (severe), achondrogenesis, and hypochondrogenesis.

Management

If the condition is suspected prenatally and diagnosed by molecular means (mutation analysis following amniocentesis), the parents should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographically confirmed, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

COL2A1 Spectrum

Spondyloepiphyseal Dysplasia Congenita

Presentation

SEDC manifests itself with shortened neck, trunk, and limbs, normal-sized hands and feet, flat facial profile, and occasional cleft palate and clubfoot (Terhal et al., 2015; Fig. 102.5). The name

spondyloepiphyseal dysplasia congenita (SEDC) is derived from the spinal (*spondylo*) and growth plate (*epiphyseal*) involvement. *Congenita* indicates that the condition is present from birth.

Radiographic Features

Radiographic features include ovoid or pear-shaped vertebral bodies in infancy, with platyspondyly more evident at a later age; odontoid hypoplasia evident in early childhood; midface hypoplasia; retrognathia; mild rhizomelia and mesomelia (see Fig. 102.5B–D); absent ossification of the os pubis; apparent decreased bone age caused by epiphyseal involvement; and development of coxa vara, variable kyphosis, and scoliosis in childhood (Spranger et al., 2012).

Etiology

SEDC is caused by mutations in the gene for type II collagen (*COL2A1*), the predominant protein building block of cartilage. Mutations in *COL2A1* are also responsible for Kniest dysplasia, some forms of spondyloepimetaphyseal dysplasia and Stickler syndrome, and the perinatal lethal disorders achondrogenesis type II and hypochondrogenesis (Spranger et al., 1994; Tiller et al., 1995; Mortier et al., 2000).

Inheritance

SEDC is inherited in an autosomal dominant pattern. Offspring of affected individuals are at 50% risk of inheriting the disorder. The recurrence risk for unaffected parents is approximately 6%, considering the possibility of parental gonadal mosaicism.

Differential Diagnosis

Differential diagnoses include the milder form of hypochondrogenesis and Morquio syndrome.

• **Fig. 102.5** Spondyloepiphyseal Dysplasia Congenita. (A) A 2-month-old infant with short neck, trunk, and limbs. Note the flat facial profile and normal size of the hands and feet. (B) Anteroposterior radiograph revealing platyspondyly and short chest. (C) Lateral radiograph revealing platyspondyly. (D) Upper limb radiograph revealing rhizomelia, mesomelia, and a normal-sized hand.

Management

Neonates may require intubation because of upper airway compromise. Care must be given when the cervical spine is manipulated (as in endotracheal intubation), because of odontoid hypoplasia. C1–C2 fusion may be required in early childhood to stabilize the cervical spine. Annual hearing screens are recommended during childhood. Regular ophthalmologic evaluation (semiannually before school age) is essential to detect early development of retinal detachment and to manage myopia. Osteoarthritis is a common feature in early adulthood, often requiring hip arthroplasty.

Achondrogenesis Type II–Hypochondrogenesis

Presentation

The severe end of the *COL2A1* spectrum manifests itself with fetal hydrops and maternal polyhydramnios, severe short trunk and limbs, and fetal or neonatal death caused by pulmonary hypoplasia.

Radiographic Features

Radiographic features include prenatal polyhydramnios, a large calvarium with normal ossification, midface hypoplasia, retrognathia, platyspondyly with underossification of the vertebral bodies (achondrogenesis type II), short chest with a protuberant abdomen, marked shortening of all tubular bones (Fig. 102.6), and small iliac wings.

Etiology

Achondrogenesis type II–hypochondrogenesis is caused by mutations in the gene for type II collagen (*COL2A1*), the predominant protein building block of cartilage (Mortier et al., 2000).

Inheritance

All cases of achondrogenesis type II–hypochondrogenesis are caused by spontaneous dominant-acting mutations in *COL2A1*. The recurrence risk has been reported to be as high as 6% because of parental gonadal mosaicism (Forzano et al., 2007). Prenatal diagnosis is available if the particular gene mutation has been previously identified in an affected individual.

Differential Diagnosis

Differential diagnoses include achondrogenesis type I and OI types II and III.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographic confirmation is obtained, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

SLC26A2 Spectrum

Diastrophic Dysplasia

Presentation

Newborns with diastrophic dysplasia exhibit limb shortening, hitchhiker thumbs, spinal deformities (especially cervical kyphosis), and contractures of the large joints (Fig. 102.7). Clubfoot and ulnar deviation of the fingers may also be present. Cystic ear

• **Fig. 102.6** Achondrogenesis Type II. (A) A 20-week fetus with small chest and short limbs. (B) Radiograph demonstrating poor ossification of vertebral bodies and short limbs.

• **Fig. 102.7** Diastrophic dysplasia. (A) Infant with prominent eyes, small chin, slightly narrow chest, proximally placed angulated thumbs, and short limbs. (B) Neonate profile showing small chin, swollen ears, and short neck. Note the proximally placed angulated thumb. (C) View of the neonate's hand showing the proximally placed angulated thumb and mild syndactyly. (Courtesy Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States.)

swelling, with subsequent inflammation and calcification, may develop in infancy. On occasion the disease can be lethal at birth, but most individuals survive the neonatal period (Bonafé et al., 2013b).

Radiographic Features

The most characteristic clinical and radiographic feature is the proximally placed hitchhiker thumb, with ulnar deviation of the fingers. Cervical kyphosis is a frequent finding. Long bones are moderately shortened and thick, with mild metaphyseal flaring, rounding of the distal part of the femur, and bowing of the radius and tibia. Severe talipes equinovarus may be present. Iliac wings are hypoplastic, with flat acetabular roofs. The chest can be narrow, bell shaped, or both. Narrowing (lack of flare) of the interpedicular distance in the lumbar spine is reminiscent of achondroplasia.

Etiology

Diastrophic dysplasia is caused by mutations in the *SLC26A2* gene (formerly referred to as the diastrophic dysplasia sulfate transporter gene, *DTDST*), which also cause the lethal disorders achondrogenesis type IB and atelosteogenesis type II, as well as a rare recessive form of multiple epiphyseal dysplasia. The gene product is a sulfate–chloride exchanger of the cell membrane (Superti-Furga et al., 1996); this affects incorporation of sulfate into proteoglycans (mucopolysaccharides), especially chondroitin sulfate B-containing proteoglycans, which are prevalent in cartilage.

Inheritance

Diastrophic dysplasia is inherited in an autosomal recessive pattern. Siblings of affected individuals are at 25% risk of inheriting an abnormal allele from both carrier parents.

Differential Diagnosis

Differential diagnoses include atelosteogenesis type II (part of the *SLC26A2* spectrum), spondyloepiphyseal dysplasia, and arthrogryposis.

Management

Mechanical ventilation may be required because of small chest circumference and a floppy airway. Maintenance of joint mobility and proper positioning through physical therapy is essential. Serial casting and/or surgical correction of clubfeet may be required. Cervical kyphosis can impede endotracheal intubation and can result in cord compression but may resolve spontaneously during infancy. Preferred treatment of auricular cysts is application of a compression mold rather than incision and drainage (Cushing et al., 2011).

Achondrogenesis Type IB

Presentation

Achondrogenesis type IB is characterized by short stature, extremely short limbs, a relatively large head with a round face, short nose, small mouth, soft skull, and a very short neck (Bonafé et al., 2013a). Polyhydramnios during pregnancy, premature delivery,

• **Fig. 102.8** Achondrogenesis Type IB. Cervical, thoracic, and lumbar vertebral bodies are not ossified, the sacrum is not ossified, the ribs are short, and the limbs are extremely short with medial femoral metaphyseal spikes. (Courtesy Elaine Zackai, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States.)

and hydrops are common. The affected infant is stillborn or dies within hours of birth.

Radiographic Features

The long bones are extremely short, with square, globular, or triangular shapes and medial spikes in the metaphyses of the femurs (Fig. 102.8). The calvarium and vertebrae are poorly ossified (type IB), and the ribs are short.

Etiology

Achondrogenesis type IB is caused by mutations in the *SLC26A2* gene (see [Diastrophic Dysplasia](#) earlier).

Inheritance

Achondrogenesis type IB is inherited in an autosomal recessive pattern. Siblings of affected individuals are at 25% risk of inheriting an abnormal allele from both carrier parents.

Differential Diagnosis

Differential diagnoses include atelosteogenesis type II (part of the *SLC26A2* spectrum), achondrogenesis type II, and hypochondrogenesis.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographic confirmation is obtained,

management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

Other Skeletal Dysplasias

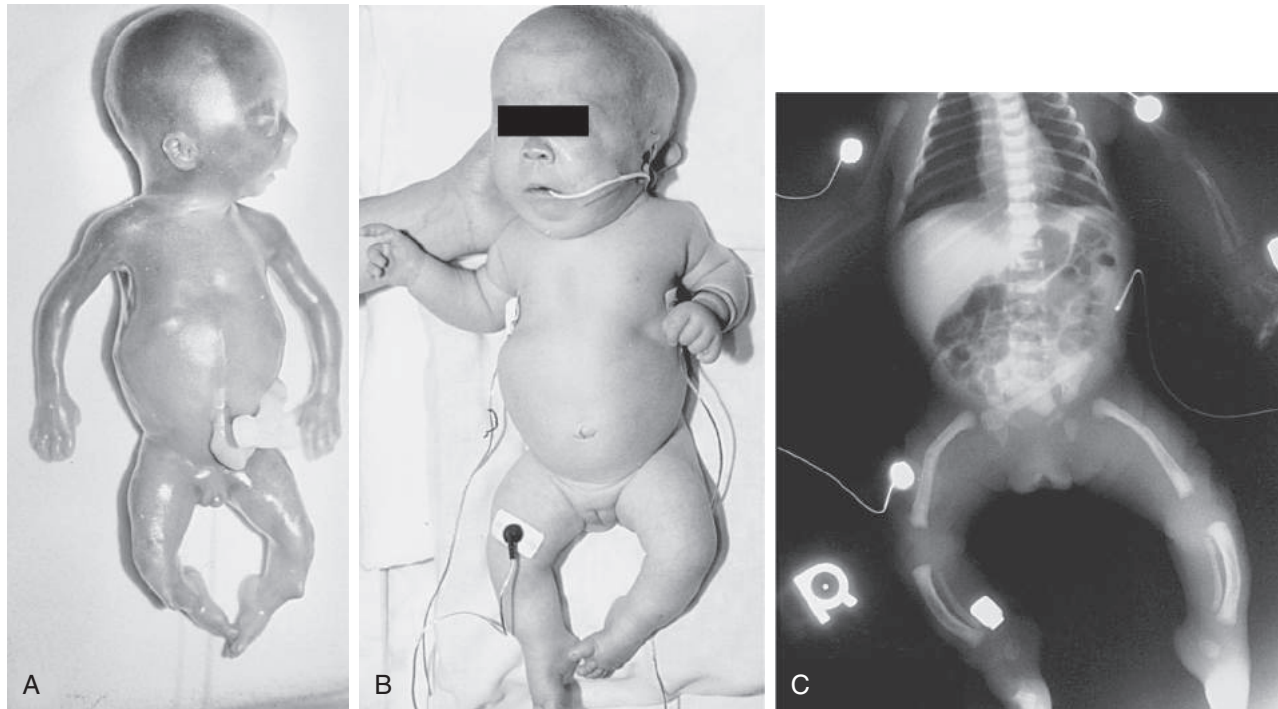

Campomelic Dysplasia

Presentation

Campomelic dysplasia is characterized by short stature (birth length of 35–49 cm), large dolichocephalic skull, large anterior fontanel, high forehead, flat face, widely spaced eyes with short palpebral fissures, low-set ears, cleft soft palate, micrognathia, relatively long and slender thighs and upper arms, short bowed legs with dimples in the midshaft (in most cases), narrow chest, and kyphoscoliosis (Fig. 102.9). Sex reversal or ambiguous genitalia affects 75% of the chromosomal males; there may be internal and external genital abnormalities (from mild anomalies to complete sex reversal) in XY males (Meyer et al., 1997). Absence of the olfactory bulbs and tracts as well as heart and renal malformations may occur. Death, usually in infancy, results from pulmonary hypoplasia, tracheomalacia, or cervical spinal instability. Rare survivors are usually globally developmentally delayed. A few more mildly affected people without bowed limbs have been reported (Unger et al., 2013).

Radiographic Features

The most characteristic finding is midshaft angulation (campomelia) of the femurs, although it is not a constant finding. Other features

• **Fig. 102.9** Campomelic Dysplasia. (A) A 22-week-old 46,XY female fetus with normal head, long philtrum, micrognathia, low-set ears, mild narrowing of the chest, proximally placed thumbs, and bowed or angulated lower limbs resembling those of osteogenesis imperfecta type II but less shortened. The external genitalia are female. (B) Neonate with the long-limb form of the disorder who has a relatively large head, micrognathia, a narrow chest, and bowing of the lower limbs with characteristic dimpling of the lower leg. (C) Radiograph showing the narrow chest, the relatively long, thin limb bones with bowing of the femurs and tibiae, and a long, narrow pelvis. (Courtesy Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States.)

include hypoplastic, undermineralized cervical vertebrae and thoracic pedicles; narrow iliac wings with dislocated hips; brachydactyly; clubfeet; anterior bowing of tibiae; bell-shaped chest with thin, wavy ribs (with only 11 pairs); and scapular hypoplasia (see Fig. 102.9C).

Etiology

Campomelic dysplasia is caused by mutations in or near the sex-determining region Y-box 9 gene (*SOX9*; Foster et al., 1994). *SOX9* is homologous to the *SRY* gene and encodes a transcription factor involved in both bone formation and testis development.

Inheritance

Campomelic dysplasia is an autosomal dominant trait. Most cases are new sporadic occurrences in a family; recurrence caused by gonadal mosaicism has been reported (Smyk et al., 2007).

Differential Diagnosis

Differential diagnoses include OI types II and III, diastrophic dysplasia, kyphomelic dysplasia, thanatophoric dysplasia, and SEDC (severe).

Management

Survival beyond the newborn period is rare; therefore support is primarily directed toward comfort measures. In survivors, care must be given to the cervical spine, which may be unstable. Chromosomal studies to determine sex and pelvic ultrasonography

to examine internal genitalia may be performed. For survivors, cleft palate may be repaired in those able to feed orally, and clubfeet may require casting or surgical correction.

Heritable Connective Tissue Disorders

Genetic disorders of connective tissue represent a large and expanding group of pleiotropic diseases that may involve the musculoskeletal, cardiovascular, and pulmonary systems as well as the eyes and skin. These diseases are caused by mutations in genes that function in extracellular matrix assembly and/or homeostasis and often result in serious clinical consequences (Donkervoort et al., 2015; Vanakker et al., 2015). Several of these disorders present in the newborn period with dramatic joint hypermobility and/or abnormal skin findings (see Table 102.3).

Early-Onset /Rapidly Progressive (Congenital; Neonatal, Infantile) Marfan Syndrome

Presentation

Infants with early-onset/rapidly progressive Marfan syndrome have a long, thin body and can have an aged appearance because of a lack of subcutaneous tissue and wrinkled, sagging skin (Morse et al., 1990; Fig. 102.10). The craniofacial features include dolichocephaly, deep-set eyes with large or small corneas (and occasionally cataracts), high nasal bridge, high palate, small pointed chin

• **Fig. 102.10** Congenital Marfan Syndrome. (A) Neonate with furrowed brow and lax facial skin, thin simple ears, small chin, short neck with redundant skin (not shown), multiple joint flexion contractures, and striking arachnodactyly of fingers and toes. The neonate also had megalocornea, pectus carinatum, mitral valve prolapse, aortic root dilation, and an *FBNI* gene missense mutation. (B) Chest radiograph revealing thin ribs and serpentine clavicles. (C) Lateral spine radiograph demonstrating exaggerated thoracic kyphosis.

with a horizontal skin crease, and large simple or crumpled ears. The fingers and toes are long and thin (arachnodactyly). Some joints are hyperextensible, and others have flexion contractures causing clubfoot, dislocated hips, or adducted thumbs. Infants tend to exhibit hypotonia with low muscle mass. Lenses are usually not subluxated at birth. The most important cause of morbidity and mortality is severe cardiovascular disease, which affects almost every neonate with congenital Marfan syndrome (cMS)—namely, mitral and tricuspid valve prolapse and insufficiency and aortic root dilation. The ascending aorta may be dilated and tortuous. Many infants die of congestive heart failure in the first year of life. Survivors have chronic hypotonia and contractures, are unable to walk, and require many surgical procedures.

Radiographic Features

Radiographic features include pectus deformity, spontaneous pneumothorax, dural ectasia, aortic root dilation, and mitral valve prolapse. Many of these features may not be present in the newborn period.

Etiology

Congenital Marfan syndrome is caused by mutations in the gene encoding fibrillin 1 (*FBNI*; Dietz et al., 1991). Fibrillin is a glycoprotein associated with microfibrils, which form linear bundles in the matrices of many tissues, such as aorta, periosteum, perichondrium, cartilage, tendons, muscle, pleura, and meninges. There are two regions in *FBNI* in which many mutations causing cMS occur; these lie among exons 24 to 27 and exons 31 and 32 (Dietz, 2017). Molecular analysis does not yield mutations in all cases.

Inheritance

Marfan syndrome is an autosomal dominant disorder. In most neonates with cMS, occurrence is sporadic within a family (Morse et al., 1990). However, there is one well-documented neonate with cMS whose father had classic Marfan syndrome except for average height (Lopes et al., 1995). There are also reports of familial cMS due to parental gonadal mosaicism (Tekin et al., 2007).

• **Fig. 102.11** (A) Congenital contractural arachnodactyly (Beals syndrome). This infant has a long, thin trunk and limbs, contractures of the joints, and crumpled ears. (B) Infant with cutis laxa. (Courtesy Montreal Children's Hospital, Montreal, Quebec, Canada.)

Differential Diagnosis

Differential diagnoses include CCA, autosomal recessive cutis laxa, and Loeys–Dietz syndrome.

Management

Patients require annual ophthalmologic and cardiac evaluation throughout childhood. Use of cardioselective beta-blockers, such as atenolol, is often implemented at the first signs of aortic root dilation. The angiotensin II antagonist losartan has also shown promise in this regard and may be used in combination with beta-blockers (Brooke et al., 2008; Dietz, 2014). Children should be screened for the development of scoliosis.

Congenital Contractural Arachnodactyly (Beals Syndrome; Distal Arthrogryposis Type 9)

Presentation

CCA (Beals syndrome; distal arthrogryposis type 9) is characterized by a thin, wasted appearance with minimal muscle and fat mass (similar to neonatal Marfan syndrome). Distinctive features include arachnodactyly with contractures of the large and small joints (Fig. 102.11A), as well as crumpled, overfolded helices of the external ear. Cardiovascular involvement is usually limited to mitral valve prolapse, but aortic root dilation may occasionally develop (Godfrey, 2012).

Radiographic Features

Features are nonspecific and include elongated proximal phalanges; contractures of digits, ankles, knees, and hips; thin, gracile tubular bones; and gradual development of kyphoscoliosis.

Etiology

CCA is caused by dominant-acting mutations in the gene encoding fibrillin 2 (*FBN2*).

Inheritance

CCA is inherited in an autosomal dominant manner, with most patients representing the result of spontaneous mutations. Offspring of affected individuals are at 50% risk of inheriting the condition. Gonadal mosaicism has been described in CCA (Putnam et al., 1997).

Differential Diagnosis

Differential diagnoses include cMS, Stickler syndrome, homocystinuria, and distal arthrogryposis.

Management

Proper nutrition is essential to ensure adequate weight gain. Joint contractures respond to physical therapy, but occasionally surgical release may be required. Surveillance for development of spinal curvature and aortic root dilation, although rare, is essential throughout childhood (Godfrey, 2012).

Ehlers–Danlos Syndromes

Presentation

The EDSs are a clinically and genetically heterogeneous group of connective tissue disorders that are characterized by various degrees of joint and skin hypermobility, excessive bruising, abnormal wound healing, and fragility of tissues (Malfait et al., 2011; Donkervoort et al., 2015). This group of disorders was formally reclassified in 1997 (Beighton et al., 1998), but several new rare variant forms

have been reported since then, and an updated reclassification is forthcoming (Donkervoort et al., 2015). The types that are more likely to present in the newborn period include the classic type (formerly type I), the kyphoscoliotic type (formerly type VI), the dermatosparaxis type (formerly type VIIc), and the arthrochalasis type (formerly types VIIa and VIIb). The classic type often presents with premature delivery of an affected fetus as a result of a rupture of the fragile amniotic membranes. The infant may be floppy and in the breech position, and there may be joint laxity and joint instability (Malfait et al., 2011). The kyphoscoliotic type often presents with severe hypotonia and scoliosis with risk of subsequent ocular involvement. In the arthrochalasis type the major involvement is of the ligaments and joint capsules. Large and small joints are hypermobile and dislocatable; severe congenital dislocation of hips occurs. The findings in the dermatosparaxis type include soft, fragile, and redundant skin with some joint hypermobility.

In vascular (formerly type IV) EDS the greatest danger is to the pregnant affected woman, for whom there is a high risk of uterine and arterial rupture. Although there is a 50% risk that the fetus will be affected, the problems of blood loss and prematurity are more important in the newborn period than the disorder itself.

Radiographic Features

Radiographic features are dependent on the particular type of EDS. Congenital hip dislocation may be evident on plain films. Hydronephrosis, bladder diverticula, and spontaneous pneumothorax may occur occasionally. Aortic dilation and arterial aneurysms may be evident by echocardiography and other imaging modalities but occur only in patients of school age or older.

Etiology

Mutations in two of the genes for type V collagen (*COL5A1* and *COL5A2*) are demonstrable in some cases of classic EDS (Malfait and de Paepe, 2005). The vascular type is caused by mutations in the gene for type III collagen (*COL3A1*). The arthrochalasis type is caused by mutations in either gene for type I collagen (*COL1A1* or *COL1A2*), which result in loss of the N-proteinase cleavage site of the protein. The kyphoscoliotic type is caused by mutations in the gene for a procollagen cross-linking enzyme (*PLOD1*). The dermatosparaxis type is caused by mutations in a gene for a procollagen proteinase (*ADAMTS2*).

Inheritance

Most types of EDSs are inherited as autosomal dominant traits. Each child of an affected person has a 50% chance of inheriting and manifesting the disorder, although there can be marked intrafamilial variability (Malfait and de Paepe, 2005). The kyphoscoliotic and dermatosparaxis types of EDSs are inherited in an autosomal recessive manner.

Differential Diagnosis

Differential diagnoses include cMS, CCA (distal arthrogryposis type 9), Larsen syndrome, and other rare variant forms of EDS (Donkervoort et al., 2015; Vanakker et al., 2015).

Management

Trauma should be avoided because of skin fragility. Effective closure of surgical wounds is challenging because of a tendency for dehiscence.

Cutis Laxa

Presentation

Cutis laxa is a group of genetically heterogeneous disorders that primarily affect the assembly and homeostasis of elastic fibers. As such, the presentation can be highly varied. Infantile forms may exhibit loose, furrowed skin, a large anterior fontanelle, hypotonia, hernias, and congenital hip dislocation (see Fig. 102.11B; Vanakker et al., 2015; Van Maldergem et al., 2015).

Radiographic Features

Radiographic features are in part dependent on the genetic form of the disorder. Nonspecific features include a large anterior fontanel, congenital hip dislocation, and hernias. The X-linked form may exhibit occipital horns of the skull. Arterial tortuosity, aortic root dilation, and cortical and cerebellar anomalies may be seen in some forms, as well as gastrointestinal tract and urinary tract diverticula.

Etiology

The relatively mild, autosomal dominant form of cutis laxa is caused by mutations in the elastin gene (*ELN*). The X-linked recessive form (occipital horn syndrome) is caused by mutations in the *ATP7A* gene (allelic with Menkes syndrome). Autosomal recessive forms may be caused by mutations in the fibulin 4 gene (*FBLN4*), the fibulin 5 gene (*FBLN5*), or the gene that encodes the A2 subunit of vacuolar H⁺-ATPase (*ATP6V0A2*). Biochemical clues as to the cause in a particular patient may include decreased serum copper and ceruloplasmin levels (X-linked form), and abnormal serum sialotransferrin isoelectric focusing results in cases caused by *ATP6V0A2* mutations.

Inheritance

Because cutis laxa is genetically heterogeneous, the modes of inheritance include autosomal dominant, autosomal recessive, and X-linked recessive. The latter two modes are usually responsible for forms with neonatal and infantile presentation.

Differential Diagnosis

Differential diagnoses include EDS, Menkes syndrome, geroderma osteodysplastica, and de Barsy syndrome.

Management

Serious childhood complications include developmental delay, pulmonary emphysema, aortic root dilation, and arterial tortuosity. Annual ophthalmologic and cardiac examinations are essential, and referral to special education programs may be indicated.

Menkes Syndrome

Presentation

Menkes syndrome often appears in the newborn period with nonspecific neurologic manifestations. Typically, developmental delay is evident in the first 2 to 3 months of life, with failure to thrive, seizures, and severe ocular manifestations. Changes in the appearance of the hair include hypopigmentation, brittleness, patchy alopecia, and twisted shafts seen by light microscopy (i.e., pili torti; Fig. 102.12A). Early death is common and may occur in infancy (Kaler, 2010). Serum copper and ceruloplasmin concentrations are low, and the plasma dopamine-to-norepinephrine ratio may be elevated (Goldstein et al., 2009).

• **Fig. 102.12** Menkes Syndrome. (A) Note the blonde hair, fair complexion, and epicanthal folds in this 11-month-old Hispanic boy. (B) Note multiple wormian bones near the occiput.

Radiographic Features

Features may evolve during infancy and may include bladder diverticula (seen on bladder ultrasonography and voiding cystourethrogram), tortuous vessels (on echocardiogram, magnetic resonance imaging with contrast agent), gastric polyps (on upper gastrointestinal [GI] contrast study), metaphyseal spurring, osteopenia, and wormian bones on plain radiographs (Lachman, 2006; see Fig. 102.12B).

Etiology

Menkes syndrome is caused by mutations in the gene encoding a copper-transporting adenosine triphosphatase (*ATP7A*; Kaler et al., 1994). This enzyme participates in the final processing of several copper-dependent enzymes, including dopamine β -hydroxylase, tyrosinase, lysyl oxidase, superoxide dismutase, and cytochrome *c* oxidase. As a result, several physiologic processes and cellular functions are impaired, including collagen cross-linking, pigment production, and neurotransmission (Goldstein et al., 2009).

Inheritance

Menkes syndrome is an X-linked recessive disorder; therefore only males are affected. Female carriers may exhibit pili torti in some hair shafts because of lyonization (Moore and Howell, 1985). Sons born to carrier females have a 50% risk of manifesting the disease.

Differential Diagnosis

Differential diagnoses include cutis laxa (the occipital horn form is allelic), EDS, neonatal cMS, biotinidase deficiency, mitochondrial myopathies, nutritional copper deficiency, and some organic acidurias.

Management

Early diagnosis allows copper supplementation therapy (Kaler, 2013), but this is not effective in all patients. Patients should be monitored for the development of seizures, as well as a propensity for bone fragility, poor wound healing, and vascular fragility leading to excessive bleeding, hemorrhagic strokes, and subdural hematomas. Bladder diverticula may result in urinary retention

and urinary tract infections and should be surgically corrected. Patients are at risk of moderate to severe developmental delay, and they should be referred to infant stimulation and early intervention programs.

Family Support and Education

Many of the conditions described in this chapter are rare, and parents (and sometimes medical staff) are unfamiliar with or bewildered by such conditions. Providing appropriate educational materials is of utmost importance for making important medical decisions and preparing for the future. Support groups such as the Little People of America (<http://www.lpaonline.org>) and the Osteogenesis Imperfecta Foundation (<http://www.oif.org>) are helpful in this regard, as the medical content is reviewed and updated by experts in the field. In addition, individual entries in GeneReviews (<https://www.ncbi.nlm.nih.gov/books/NBK1116/>) frequently include links to support groups as well as to educational pieces written in lay language, such as the NIH Genetics Home Reference (<https://ghr.nlm.nih.gov/condition>).

Newborn Skin Development:
Structure and Function

ROBERT SIDBURY

KEY POINTS

- Healthy full-term infant skin is well developed and serves as an effective barrier. Premature infants, especially those of very low birth weight, have an ineffective barrier that increases risk of invasive infection, dehydration, cutaneous injury, and toxic absorption.
- Birthmarks may have neurologic implications that require magnetic resonance imaging. In some cases newborns and very young infants can be imaged using a “feed and wrap” technique without sedation. Awareness of this window of opportunity may help avoid unnecessary general anesthesia.
- Early application of emollients in certain infants can improve barrier function, decrease risk of infection, and potentially prevent atopic outcomes.
- Blaschko's lines are patterns formed by migration of skin cells during embryogenesis. They are distinct from dermatomes. Cutaneous findings in this distribution are a clue to an underlying mutational event.

The skin serves several critical roles including primary barrier against infection, thermoregulation, and electrolyte homeostasis. Disruption as a result of genetic mutation, injury, or prematurity can be life-threatening. This chapter details the stages of human skin development, the potential challenges of prematurity, and an approach to important clinical presentations.

Cutaneous morphogenesis is complex and incompletely understood. Advances have come from traditional murine model work but also in “reverse” by identifying mutations causing disorders that manifest with developmental defects (e.g., aplasia cutis congenita) (Shimomura, 2016). Human skin develops from apposed tissue of both mesodermal and ectodermal origin. From mesoderm arise fibroblasts, vascular cells, adipocytes, and immune-presenting Langerhans cells, which ultimately reside in the epidermis. Ectoderm-derived tissue includes keratinocytes and neural crest-derived melanocytes. The assembly of the epidermis, dermoepidermal junction (DEJ), dermis, and fat, along with epidermal appendages and immigrant cells, is a complex dynamic with potential for clinically significant disruption at every step. Table 103.1 enumerates

these critical stages. The clinician can use this ontogeny to guide assessment: any newborn with evident cutaneous pathology should prompt additional scrutiny of hair, nails, teeth (natal teeth can suggest specific disorders), and the central nervous system.

Epidermis

The epidermis derives entirely from ectoderm. A single-layered epithelium spans the embryo from gastrulation. Subsequent development proceeds in discrete stages: embryonic (5–8 weeks), embryonic/fetal transition (9–10 weeks), then to early (11–14 weeks), mid (15–20 weeks), and late (20 weeks–birth) fetal period (Holbrook and Odland, 1975). Differentiation and formation of appendages occurs predominantly during the second trimester. It is during the late fetal stage that the skin first becomes functional. The stratum corneum, or outer epidermis, has been likened to “bricks and mortar” (Elias, 1983). Epidermal keratinization begins first on the head, face, and palms. Anucleate corneocytes flatten and form “bricks,” while a mixture of cells, adhesion proteins, and lipids form the semipermeable mortar. One such protein, filament aggregating protein, or filaggrin, has recently been linked to atopy. Patients with filaggrin mutations are at greater risk for eczema, asthma, and allergies (Palmer et al., 2006). Decreased ability to retain moisture with resulting fissures in the stratum corneum may promote epicutaneous allergen exposure and sensitization. Emerging evidence suggests that early aggressive application of thick emollients to at-risk infants decreases their chance of developing atopic dermatitis (Simpson et al., 2014).

Dermoepidermal Junction

The DEJ is the interface between basal layer keratinocytes of the epidermis and the dermis and helps the skin resist shearing forces. The critical elements of the DEJ form by 8–10 weeks of gestation. The DEJ is comprised of hemidesmosomes, anchoring filaments, anchoring fibrils, and type VII collagen, which combine to tether the dermis to the epidermis (Fig. 103.1). Epidermolysis bullosa (EB) is an inherited disorder of cutaneous fragility that results from defective proteins in this complex. The type of EB depends on the affected protein, and outcomes can vary widely.

TABLE 103.1 Milestones in Fetal Skin Embryogenesis

| Milestone | Gestational Week |
|--|------------------|
| Expression of epidermal keratins | 6 |
| Development of specialized cells including melanocytes, Langerhans | 8 |
| Formation of dermoepidermal junction | 8–10 |
| Beginning of nail development | 10 |
| Beginning of hair development | 12 |
| Palmoplantar sweat gland formation | 10–12 |
| Formation of fat in subcutis | 15 |
| Sweat gland formation in rest of body | 24–26 |

Dermis and Subcutis

The dermis is derived from diverse tissue types. Embryonic mesenchymal cells capable of becoming multiple cell types are enmeshed in a hyaluronic matrix called a *cellular dermis*. At 8 weeks' estimated gestational age (EGA) dermis is distinguishable from underlying tissue. By 15 weeks collagen fibers accumulate, and by 22–24 weeks elastin fibers are first detectable by electron microscopy (Holbrook and Odland, 1975). Immature dermis will not scar when traumatized (such as with a fetal skin biopsy), whereas the increasing tensile strength that accompanies maturation also connotes potential to scar; this occurs at roughly the end of the second trimester. Blood vessel plexi are discernible by 12 weeks' EGA but do not fully mature until after birth. Vasculogenesis, the formation of endothelial cells and then vessels from angioblasts, has been completed by 20 weeks' gestation; angiogenesis follows as existing vessels give rise to new ones. Sprouting angiogenesis may add new

vessels to tissue previously lacking vascularity; this involves spouts of endothelial cells growing toward an angiogenic stimulus such as vascular endothelial growth factor or basic fibroblast growth factor. Intussusceptive angiogenesis is characterized by a splitting process where the vessel wall invades the lumen, causing the vessel to divide in two. This type of angiogenesis occurs only in areas of preexisting vascularity. Both types of angiogenesis can occur in virtually all tissues and organs (Adair and Montani, 2010). Neural networks develop toward the end of the first trimester and follow a vascular pattern. Adipose tissue develops beneath the dermis, starting in the second trimester (Visscher et al., 2015).

Goltz syndrome (focal dermal hypoplasia) is an X-linked dominant disorder caused by mutations in *PORCN*. Affected individuals are 90% female and manifest with striking linear atrophic plaques with distinctive fat herniation due to dermal atrophy.

Appendages

Hair, nail, sweat gland, and apocrine gland development relies on coordinated dermal–epidermal interaction that commences around 10 weeks' gestation. Hair follicle formation is initiated in the dermis, which directs overlying epidermal basal cells to aggregate in the form of a placode. Hair follicles differentiate during the second trimester, and hair canals are formed by 20 weeks when scalp hairs are just visible. Hairs cycle between growth (anagen), resting (catagen), and shedding (telogen). The first shedding cycle occurs around 28 weeks' gestation, after which they reenter anagen phase. The final shedding phase generally occurs postnatally, at the occiput, leading to occipital alopecia often misattributed to pressure or friction.

Nails begin development at 8 weeks' EGA, slightly earlier than the hair follicles. A keratinized nail has completely covered the nail plate by 5 months' EGA. Hair and nail keratins have greater structural integrity than those in the epidermis.

Sebaceous glands develop contemporaneously with hair follicles. At 13–16 weeks' EGA characteristic sebaceous gland bulges can be seen with hair follicles, just above the insertion of the arrector pili muscle. Maternal hormones induce sebaceous gland production of sebum during the late second and third trimester. Sebum and shed corneocytes form vernix, which progressively coats the fetus in a cephalocaudal orientation. Fetal lung maturity parallels sebaceous gland activity, and increased physiologic concentrations of surfactant emulsifies surface vernix.

Palmoplantar eccrine sweat glands begin to develop at 55–65 days' gestation and are fully developed by the second trimester. Interfollicular sweat glands and apocrine glands do not form until midsecond trimester. Ectodermal dysplasias are a heterogeneous group of disorders with striking abnormalities in skin appendages. Hydrotic ectodermal dysplasia, or Clouston syndrome, is due to mutations in *GJB6* (connexin 30), which directs formation of gap junctions found notably in adnexal structures.

Specialized Skin Cells

Melanocytes, Langerhans cells, and Merkel cells comprise the primary epidermal immigrant cells. Melanocytes derive from the neural crest and migrate along Blaschko's lines to populate the entire fetal epidermis. Melanocytes are first identifiable at 50 days' EGA and are fully present at birth, but melanogenesis continues such that skin is not fully pigmented at birth and will darken in the first months. Blaschko's lines are distinct from dermatomes, and clinical abnormalities in this distribution can be helpful diagnostically (Fig.

• Fig. 103.2 Blaschko's Lines or Developmental Lines of Epidermal Migration.

103.2). Incontinentia pigmenti, an X-linked dominantly inherited gene dermatosis due to mutations in *NEMO*, presents with a series of cutaneous findings over time, first vesicles and then a warty hyperkeratotic phase, followed by dyspigmentation all along Blaschko's lines. Knowledge of this pattern can help discriminate from fundamentally different processes such as herpes zoster, which would present with vesicles in a dermatomal distribution.

Langerhans cells first appear at 40 days' gestation and serve as antigen-presenting cells. Merkel cells appear at 8 weeks' gestation and serve a mechanoreceptor function.

Epidermal Stem Cells

The skin must constantly repair and renew itself. There are several different types of stem cells within the skin including basal keratinocytes, hair follicles, and melanocytes. Basal keratinocytes can be grown in sheets and used for therapeutic barrier purposes in burn and chronic wound patients (e.g., in EB). Such grafts are useful but do not contain appendages such as hair follicles or sweat glands. Improved understanding of the interaction among various cutaneous stem cells, their microenvironments, and their pluripotent is driving advances in stem cell technology (Hsu and Fuchs, 2014).

Impact of Prematurity

The stratum corneum reaches functional maturity around 33 weeks' EGA. The combination of a developmentally and functionally incompetent barrier, absence or diminished vernix caseosa, large body surface area to mass ratio, and an immature immune system places premature infants, particularly those born at less than 33 weeks' gestation, at significant risk for invasive infection and skin injury. A unique consideration in premature infants is the risk of percutaneous toxicity. Topical medications, cleansers, and even emollients (e.g., lactic acid) can lead to dangerous systemic levels

| TABLE 103.2 The Impact of Prematurity on Skin Physiology | | |
|--|--|--------------------------|
| | Premature | Term |
| Skin thickness | 0.9 mm | 1.2 mm |
| Epidermal thickness | 20 μ | 40 μ |
| Epidermal covering | No vernix before 28 weeks | Vernix |
| TEWL | High (at 26 weeks TEWL = 45 g/m per h) | Low (TEWL = 5 g/m per h) |
| Acid mantle | Incomplete | Complete |
| Percutaneous Absorption | Very high | Normal |

TEWL, Transepidermal water loss.

in premature infants. A particularly seductive risk is that of cutaneous anesthesia when used for small invasive procedures. Minimizing pain is important, but careful attention to safe limits of topical anesthetic is vital (Tran and Koo, 2014). Table 103.2 compares premature and term infant skin. Table 103.3 summarizes important potential cutaneous absorption risks.

Care of Newborn Skin

Emollients can serve several purposes beyond epidermal hydration. Application of cream-based emollients in infants older than 29 weeks' EGA has been shown to enhance skin barrier development (Keichl-Kohlendorfer et al., 2008). In infants at high risk for atopic dermatitis, early application of an emollient decreased the incidence

**TABLE
103.3****Reported Hazards of Percutaneous Absorption in the Newborn**

| Compound | Reference | Product | Toxicity |
|------------------------------------|---|--|--|
| Aniline | Rutter, 1987 | Dye used as a laundry marker | Methemoglobinemia, ^a death |
| Mercury | Dinehart et al., 1988 | Diaper rinses, teething powders | Rash, hypotonia |
| Phenolic Compounds | | | |
| Pentachlorophenol | West et al., 1981 | Laundry disinfectant | Tachycardia, sweating, hepatomegaly, metabolic acidosis, death |
| Hexachlorophene | — | Topical antiseptic (pHisoHex) | Vacuolar encephalopathy, death |
| Resorcinol | West et al., 1981 | Topical antiseptic | Methemoglobinemia ^a |
| Boric acid | Goldbloom and Goldbloom, 1953 | Baby powder | Vomiting, diarrhea, erythroderma, seizures, death |
| Lindane | Rutter, 1987; West et al., 1981 | Scabicide | Neurotoxicity |
| Salicylic acid | Abidel-Magid and El Awad Ahmed, 1994; West et al., 1981 | Keratolytic emollient | Metabolic acidosis, salicylism |
| Isopropyl alcohol (underocclusion) | Rutter, 1987 | Topical antiseptic | Cutaneous hemorrhagic necrosis |
| Silver sulfadiazine | Payne et al., 1992 | Topical antibiotic (Silvadene) | Kernicterus (sulfa component), argyria (silver component) |
| Povidone–iodine | Rutter, 1987; West et al., 1981 | Topical antiseptic (Betadine) | Hypothyroidism, goiter |
| Neomycin | Rutter, 1987 | Topical antibiotic | Neural deafness |
| Corticosteroids | Rutter, 1987; West et al., 1981 | Topical antiinflammatory (Lotrisone) | Skin atrophy, adrenal suppression |
| Benzocaine | Gelman et al., 1996 | Mucosal anesthetic (teething products) | Methemoglobinemia ^a |
| Prilocaine | Frayling et al., 1990; Reynolds, 1996 | Epidermal anesthetic (EMLA) | Methemoglobinemia ^a |

^aHeritable glucose-6-phosphate deficiencies are associated with an increased susceptibility to methemoglobinemia, as is coadministration of several drugs such as sulfonamides, acetaminophen, nitroprusside, phenobarbital, and phenytoin.
EMLA, Eutectic mixture lidocaine anesthetic.

of that disorder at 6 months of age by 50% (Simpson et al., 2014). Sunflower seed oil application reduced the incidence of nosocomial infections by 41% when applied to infants less than 33 weeks' EGA in a study from Bangladesh (Darmstadt et al., 2005). Oils such as safflower, sesame, coconut, and apricot contain fatty acids that may have antiinflammatory and antibacterial properties. Olive oil can promote pityrosporum growth so it may not be the optimal choice (Siegfried and Glenn, 2012). Box 103.1 details general principles of neonatal skin care.

Bathing newborns has myriad potential hygienic, social, and cultural benefits but can potentially be detrimental to newborn skin. The timing of vernix removal varies considerably. Vernix is a complex mixture of water, protein, and lipids. Vernix is hydrophobic and hydrating and contains lysozyme and lactoferrin, which are antimicrobial. Delayed bathing of newborns beyond 6 hours after birth is recommended by the World Health Organization in high-risk settings. The pH of the skin surface of term and preterm infants is more alkaline (6.5–7.5) but declines in the 1st week to values comparable to adult skin (4.0–5.5). The establishment of this “acid mantle” is important for many reasons and can be interrupted or delayed by use of alkaline or irritating soaps. Gentle cleansers, neutral in pH, and lacking fragrances and excessive preservatives or abrasives, can be used safely. Caregivers should practice good hand hygiene, preferably with chlorhexidine, for bacterial decontamination, though 10% povidone–iodine is

advantageous for *Candida* species. Chlorhexidine may provide the most effective agent for umbilical stump care to prevent omphalitis and sepsis. Chlorhexidine 0.5% is superior to povidone–iodine in reducing peripheral catheter colonization in neonates (Visscher et al., 2015).

Morphologic Approach to Skin Pathology

Any skin examination should begin by attempting to identify a primary morphology. This helps to limit differential diagnosis and avoid the diagnostic confusion that can arise from secondary findings such as erosions and ulcerations (Table 103.4). Newborns present most commonly with benign, transient skin findings. These and other common neonatal presentations are detailed in subsequent chapters. There are several distinctive presentations that are important for pediatricians and neonatologists to recognize.

Collodion Membrane

Collodion membrane (CM) is a congenital cutaneous phenotype that has both immediate and longer term implications (Prado et al., 2012). Clinically, a “collodion baby” presents with a tight “plastic wrap–”like encasement on the skin (Fig. 103.3). This taut skin can lead to eversion of the lips (eclabium) and eyelids (ectropion) as well as dysregulation of cutaneous homeostasis, mandating

• BOX 103.1 Proposed Guidelines for Basic Skin Care in the Newborn

Use adhesives sparingly.

- Place protective dressing (e.g., DuoDerm or Tegaderm) at sites of frequent taping (endotracheal tube and nasogastric tube placement).
- Use nonadhesive electrodes, and change them only when they become nonfunctional.

Limit bathing

- Defer initial cleansing until body temperature has stabilized.
- Avoid cleansing agents for the first 2 weeks.
- Use warm water and moistened cotton pledgets in a humid environment.
- Surface cleansing is required no more than twice per week.
- If antimicrobial skin preparation is required, use short-contact chlorhexidine (except on the face).

Be aware of the composition and quantity of all topically applied agents.

- These agents include antimicrobial cleansers, diaper wipes, adhesive removers, and perineal products.
- Dispense from single-use containers, if possible.

Ensure adequate intake of protein, essential fatty acids, zinc, biotin, and vitamins A, D, and B.

- Erosive periorificial dermatitis is a sign of nutritional deficiency.

Apply a simple cream or ointment emollient every 8 hours.

Guard against excessive thermal and ultraviolet exposure.

- Use thermally controlled water for bathing.
- Avoid surface monitors with metal contacts.
- Use Plexiglas shielding over daylight fluorescent phototherapy.

Protect sites of cutaneous injury with the appropriate occlusive dressing.

- Use a film dressing on nonexudative sites.
- Use a hydrogel dressing on exudative wounds.
- Maintain appropriate hydration at the skin–dressing interface.
- Remove necrotic debris with each dressing change.

• **Fig. 103.3** A Newborn With Taut Skin Representing a Collodion Membrane.

exfoliation of the newborn). Diagnosis may be facilitated by skin biopsy and/or genetic testing, but evolution of the skin examination over time may also point toward the ultimate diagnosis noninvasively.

Vesicopustular and Bullous Eruptions

An infant born with widespread vesicles, pustules, bulla, or erosions presents a daunting differential diagnosis (Box 103.2) including infectious, inflammatory, metabolic, and genetic disorders (Avram et al., 2007). Treatable infectious etiologies such as herpes simplex virus (HSV), varicella, *Staphylococcus aureus*, and candida infections should be first ruled out by careful history and cultures. Subsequent consideration may be given to other dermatoses including mastocytosis and histiocytosis. Transient benign dermatoses that present with a vesicopustular morphology such as erythema toxicum (Fig. 103.4) or transient neonatal pustular melanosis (TNPM) should be considered and may be identified by simple laboratory studies (e.g., eosinophils on smear of erythema toxicum vs neutrophils on smear from TNPM). Widespread blistering and erosion, particularly at friction-prone areas such as the hands and feet, raise the uniquely important specter of EB (Fig. 103.5). EB is an inherited disorder of cutaneous fragility, and early awareness can avoid unnecessary iatrogenic exacerbation because of inappropriate handling, adhesives, leads, or monitors (Gonzalez, 2013). It is impossible to determine EB subtype from clinical examination alone. Relatively mild blistering at birth can occur in infants with severe subtypes so providers should be cautioned against trying to predict eventual phenotype based upon initial presentation.

Blueberry Muffin Baby

A so-called blueberry muffin baby presents with distinctive red-purple macules, papules, and plaques that have historically prompted consideration of congenital infections recalled by the TORCH acronym: *Toxoplasmosis*, *Other*, *Rubella*, *Cytomegalovirus* and *HSV*. These entities should be ruled out by history, evaluation, appropriate cultures, and supportive findings such as dysmorphism. Several noninfectious conditions should be added to the clinical differential. Histiocytosis, neuroblastoma, leukemia cutis, transient myeloproliferative disorder, mastocytosis, and multifocal vascular

TABLE 103.4 Morphologic Approach to Diagnosis

| Morphology | Description | Example |
|---------------|---|--|
| Macule/patch | Flat, no epidermal change | Capillary malformation |
| Papule/plaque | Raised, discrete edge, epidermal change | Superficial hemangioma |
| Nodule/tumor | Raised, sloping border, no epidermal change | Dermoid cyst |

| Pustule | Turbid, fluid filled | Candidiasis |
| Wheal | Edematous, red plaque | Neonatal onset multiinflammatory disease |

careful monitoring of fluids, electrolytes, and thermoregulation. Affected infants should be kept in the neonatal intensive care unit in a controlled environment as the membrane spontaneously sheds over the first weeks after birth. The majority of CM infants will ultimately have some form of chronic skin disorder, most commonly autosomal recessive congenital ichthyosis; however, other disorders including Gaucher disease and ectodermal dysplasia can present as CM. Rarely, CM infants may go on to have normal skin (lamellar

lesions can all mimic blueberry muffin lesions (Wolfe et al., 2003). A skin biopsy may be necessary to discriminate and appropriately triage such infants.

Erythroderma

Erythroderma is defined as diffuse erythema with or without associated findings like scaling. Newborns have extremely reactive skin so it may take time to discern normal physiologic change, including cutis marmorata, from actual pathology. Diffuse erythema can herald many underlying conditions, and appropriate assessment must be comprehensive, not unlike the approach to a newborn with vesicles and pustules. While infectious causes of erythroderma are less common, all treatable triggers should be eliminated. More commonly, erythroderma in a newborn may herald genetic or inflammatory conditions such as ichthyosis, psoriasis, or seborrheic dermatitis. Metabolic disorders, primary immunodeficiency, and autoinflammatory syndromes must also be considered. Timely

• Fig. 103.4 Small Eosinophil-Rich Pustules on an Inflamed Base Consistent With Erythema Toxicum.

• Fig. 103.5 Blistering on the Foot of a Newborn With Epidermolysis Bullosa.

assessment is essential even when infectious etiologies have been ruled out, as timely intervention can mitigate morbidity in some disorders (such as Menkes disease) (Galve et al., 2012).

Birthmarks With Neurologic Implications

Large congenital melanocytic nevi may be associated with neurocutaneous melanosis (NCM) (Fig. 103.6). The risk of NCM is increased if the nevus is located on the scalp, or anywhere in the midline, or if infants have multiple (>20) satellite nevi. Magnetic resonance imaging (MRI) with and without contrast is necessary to rule out NCM. Early infancy may offer a unique opportunity to obtain unsedated (feed and wrap) MRI, potentially avoiding general anesthesia later (Antonov et al., 2016).

• **Fig. 103.6** Giant Melanocytic Nevus on the Back.

Cutaneous stigmata, including pigmented or vascular lesions, excessive hair, or abnormal dimpling/clefting in the midline sacrum, can all herald underlying occult spinal dysraphism (OSD). Two or more such lesions, dimples more than 5 mm at the base, or farther than 2.5 cm from the anus all increase OSD risk (Kriss and Desai, 1998). Ultrasound, before complete vertebral ossification, can permit assessment of the brain and spine; however, the false negative rate is high.

Facial vascular anomalies such as capillary malformations may herald underlying ipsilateral angiomatosis and glaucoma (Sturge–Weber syndrome). An MRI with contrast may show leptomeningeal malformation that can predispose toward seizures and developmental delay. Computed tomography may show “tram-track calcifications” in the temporal and occipital cortex though these may not be present initially.

Segmental infantile hemangiomas, also typically on the face, can be associated with posterior fossa abnormalities such as Dandy–Walker malformation and cerebral artery dysmorphology, which predispose toward stroke, aortic coarctation, and ocular abnormalities (PHACE syndrome) (Garzon et al., 2016) (Fig. 103.7). An MRI with angiography looking for distinctively

• **Fig. 103.7** Large Segmental Infantile Hemangioma in the Setting of PHACE Syndrome.

tortuous, dysmorphic cerebral vessels can be diagnostic. As noted earlier, the potential for unsedated feed and wrap imaging may exist.

Congenital and Hereditary Disorders of the Skin

CHERYL B. BAYART AND HEATHER A. BRANDLING-BENNETT

KEY POINTS

- Genodermatoses are a broad spectrum of heritable disorders that affect the skin and may or may not affect other organ systems.
- Classification and nomenclature of these disorders are evolving as we learn more about the genetic basis and pathogenesis of these conditions.
- Genodermatoses that present in the neonatal period are discussed in this chapter.

Heritable disorders of the skin, also known as *genodermatoses*, encompass a diverse array of conditions that can affect the color, texture, and structural integrity of the epidermis, epidermal appendages, and connective tissue. Some of these diseases affect only the skin, but many are associated with anomalies of other organ systems. Knowledge of the molecular genetic basis of the genodermatoses is rapidly evolving, with the hope that this will lead to novel and more efficacious therapies. Table 104.1 provides a list of resources and support groups for patients with genodermatoses and their families.

Genetic mosaicism refers to an organism composed of two or more genetically distinct populations of cells. Mosaicism affecting the skin can lead to unique cutaneous patterns. One example of this is Blaschko lines, which refers to a linear and whorled pattern with midline demarcation, thought to represent migration of embryonic cells (Fig. 104.1; Lombillo and Sybert, 2005). Blaschko lines are different from dermatomes, skin tension lines, or lines of lymphatic drainage. There are various heritable skin disorders that present with skin lesions that follow Blaschko lines, including pigmentary disorders, incontinentia pigmenti (IP), and Goltz syndrome, which will be discussed in this chapter.

Ichthyoses

The ichthyoses, also referred to as *disorders of keratinization or cornification*, are a group of skin disorders that are characterized by scaly skin and/or hyperkeratosis (thickened stratum corneum). Historically they have been classified by their clinical and sometimes histologic features, but nosology is evolving as the molecular basis of these disorders is being discovered. In 2009 an international consensus conference was held to revise the nomenclature and

classification of inherited ichthyoses, which were subdivided into two principal groups: nonsyndromic and syndromic forms, summarized in Tables 104.2 and 104.3, respectively, with exceedingly rare or minor variants that are beyond the scope of this chapter (Oji et al., 2010). The most striking neonatal presentations are discussed next.

Collodion Baby

The term *collodion baby* refers to a neonate born encased in shiny, thickened skin that resembles parchment or plastic wrap (Fig. 104.2). The taut skin leads to various distorting features such as ectropion (eversion of eyelids), eclabium (eversion of lips), flattening or hypoplasia of the nose and ears, and pseudocontractures of the digits. These infants have an ineffective cutaneous barrier against transepidermal water loss and invasion of pathogenic organisms and are at risk of multiple complications, including temperature instability, dehydration, electrolyte instability, infections, poor sucking, failure to thrive, keratitis, ear canal obstruction, percutaneous toxicity from topical medications, pneumonia from aspiration of squamous material in amniotic fluid, and distal limb or digital ischemia (Prado et al., 2012).

These neonates need diligent supportive care in a humidified incubator with close monitoring of temperature, fluid and electrolyte balance, and caloric intake. Surveillance for signs of cutaneous or systemic infection is important, but prophylactic antibiotics or antifungals are not recommended. Skin care is somewhat controversial, but many advocate application of a bland petroleum-based or water-in-oil emollient at least every 6 to 8 hours. Caution is advised with use of topical medications or keratolytics because of increased percutaneous absorption and risk of toxicity. If there are erosions or fissures, bathing with normal saline may be more comfortable than with plain water. Ophthalmology and otolaryngology consultations should be considered for eye and ear involvement (Prado et al., 2012).

Collodion baby refers not to a specific disease but rather to an initial phenotype seen in several forms of ichthyosis (Table 104.4). Ichthyosis prematurity syndrome, Netherton syndrome (NS), and Sjögren–Larsson syndrome must also be considered in the differential diagnosis. The collodion membrane is typically shed in 3 to 4 weeks, and the eventual phenotype depends on the underlying genetic mutation. More than half of collodion babies have autosomal

recessive congenital ichthyosis (ARCI), discussed in more detail later. About 10% have almost normal skin after the collodion membrane sheds, which has been referred to as *self-healing collodion baby*. It is difficult to predict the long-term prognosis during the neonatal period. The diagnostic work-up should include a detailed family history and consideration of microscopic examination of scalp and eyebrow hair to look for tiger-tail banding seen on polarized microscopy in trichothiodystrophy (TTD). The role of skin biopsy before the collodion membrane has shed is controversial, and the underlying diagnosis may become evident with time, which will help determine appropriate genetic testing or the need for biochemical or metabolic assays.

• **Fig. 104.2** Collodion baby born encased in shiny, thickened skin that resembles plastic wrap.

Autosomal Recessive Congenital Ichthyosis: Harlequin Ichthyosis, Lamellar Ichthyosis, and Nonbullous Congenital Ichthyosiform Erythroderma

ARCI encompasses a spectrum of nonsyndromic autosomal recessive ichthyoses that includes phenotypes ranging from lamellar ichthyosis (LI) to nonbullous congenital ichthyosiform erythroderma (CIE) to harlequin ichthyosis (HI).

The classic LI phenotype is characterized by coarse, yellow to brown-black, platelike scales (Fig. 104.3) with varying degrees of underlying erythema, ectropion, and eclabium. Many patients with LI are born with a full or partial collodion membrane, discussed earlier. The classic CIE phenotype is characterized by more prominent erythroderma and finer, white scales that may not be apparent until the collodion membrane sheds. Neonates with CIE

TABLE 104.2 Nonsyndromic Inherited Ichthyoses

| Disorder | Inheritance | Gene(s) | Newborn Cutaneous Features | Childhood/Adult Cutaneous Features | Extracutaneous Features |
|---|-----------------|---|---|--|---|
| Common Ichthyoses | | | | | |
| Ichthyosis vulgaris | AD ^a | <i>FLG</i> | Onset usually after 2 to 6 months of age | Generalized scaling; hyperlinear palms and soles | Association with atopy |
| Recessive X-linked ichthyosis | XLR | <i>STS</i> | May have mild scaling and/or erythroderma or mild collodion membrane | Generalized brown or gray rhomboid or fine scaling sparing folds; prominent neck involvement; abates in summer | Cryptorchidism (5%–20%); corneal opacities (~50%); prolonged labor; contiguous gene syndromes |
| Autosomal Recessive Congenital Ichthyosis, Major Types^b | | | | | |
| Lamellar Ichthyosis | AR | <i>TGM1, ALOXE3, ALOX12B, ABCA12, CERS3, CYP4F22, NIPAL4 (ICHTHYIN), PNPLA1</i> | Collodion membrane; ectropion; eclabium | Generalized large platelike scaling; palmoplantar keratoderma, with or without scarring alopecia; hypohidrosis | With or without short stature |
| Congenital ichthyosiform erythroderma | AR | <i>TGM1, ALOXE3, ALOX12B, ABCA12, CERS3, CYP4F22, NIPAL4 (ICHTHYIN), PNPLA1, LIPN</i> | Mild scaling and erythroderma or mild collodion membrane | Erythroderma with fine scaling; with or without scarring alopecia; hypohidrosis | With or without short stature; failure to thrive |
| Harlequin ichthyosis | AR | <i>ABCA12</i> | Severe collodion membrane with armor-like scales; ectropion; eclabium; contractures | Erythroderma with fine scaling similar to that in congenital ichthyosiform erythroderma; scarring alopecia; skin infections; severe hypohidrosis | Contractures; failure to thrive; short stature |
| Keratinopathic Ichthyosis, Major Types^b | | | | | |
| Epidermolytic ichthyosis | AD | <i>KRT1, KRT10</i> | Erythroderma, bullae, or erosions, mild scaling | Thick, verruciform scale accentuated in areas of friction; PPK; bacterial colonization/infections | With or without growth failure |
| Superficial epidermolytic ichthyosis ^c | AD | <i>KRT2</i> | Erythroderma, widespread superficial bullae or erosions | Fine molting scale | None |
| Ichthyosis with confetti-like spots ^d | AD | <i>KRT1, KRT10^e</i> | Erythroderma with fine scaling; PPK | Similar to epidermolytic ichthyosis with pale confetti-like spots | With or without growth failure |
| Other Types of Ichthyosis | | | | | |
| Loricrin keratoderma | AD | <i>LOR</i> | Congenital ichthyosiform erythroderma-like or collodion membrane | Honeycomb PPK with digital constriction (pseudoainhum); generalized mild scaling accentuated over joints | None |
| Erythrokeratoderma variabilis ^f | AD | <i>GJB3, GJB4</i> | Persistent cutaneous findings may be present at birth or within the first year. | Transient, migratory erythematous patches with fine scale and fixed, well-demarcated, hyperkeratotic plaques; with or without PPK | None |

• **Fig. 104.3** Three-week-old male with generalized large scales characteristic of lamellar ichthyosis after shedding of collodion membrane.

often have a less severe collodion membrane or may be born without a membrane (Oji et al., 2010). The principles of neonatal management for these phenotypes are the same as those discussed earlier for a collodion baby.

HI is the most severe clinical phenotype of ichthyosis in a newborn. These neonates are born with an “armor” of thick, fissured, platelike scales (Fig. 104.4). They have severe ectropion and eclabium and flattened, hypoplastic nose and ears. Constricting bands lead to contractures and digital ischemia. They are at high risk of the complications discussed earlier for collodion babies but have a higher rate of infant mortality. Historically, almost 50% of babies with HI have died in the neonatal period, more than half in the first 3 days of life. The cause of death is most commonly attributed to sepsis and/or respiratory failure (Rajpopat et al., 2011). Intensive, multidisciplinary, supportive care as detailed earlier for collodion babies is critical for neonates with HI. Early initiation of therapy with a systemically acting retinoid (such as isotretinoin, 0.5 to 1 mg/kg per day, or acitretin, 0.5 mg/kg per day) before day of life 7 may improve the survival rate. Topical retinoids and surgical release of constricting bands may also be considered (Milestone and Choate, 2013). Patients who survive infancy have a lifelong ichthyosis that resembles CIE.

Modified from Prado R, Ellis LZ, Gamble R, Funk T, Arbuckle HA, Bruckner AL. Collodion baby: an update with a focus on practical management. *J Am Acad Dermatol.* 2012;67: 1362–1374.

hyperkeratosis or *bullous CIE*, presents with generalized erythroderma and bullae. The term *epidermolytic hyperkeratosis* describes the histopathologic or ultrastructural features seen on skin biopsy characterized by marked hyperkeratosis (thickened stratum corneum) with clumping and lysis (disintegration) of the epidermal cells above the basal layer (Ross et al., 2008). Newborns with EI typically present with widespread erythema and superficial blistering, as a result of the fragility of the epidermis from abnormal keratin production (Fig. 104.5). These neonates may receive a misdiagnosis of epidermolysis bullosa (EB) or staphylococcal scalded skin syndrome. Subtle skin thickening over the elbows, knees, palms, or soles may be diagnostic clues. During the first few months of life, the phenotype gradually evolves into more pronounced skin thickening with verruciform, ridged scales, accentuated in areas of friction, including flexural and intertriginous areas. Malodorous bacterial colonization is common.

Treatment of neonates with EI requires supportive care with attention to gentle handling to minimize blister formation, including use of nonadherent dressings. They are at risk of temperature instability, dehydration, and electrolyte instability and should be closely monitored for bacterial infections.

EI is caused by autosomal dominant mutations in *KRT1* or *KRT10*, either inherited or caused by a spontaneous mutation. It is also possible that the parent of a child with EI may have a congenital epidermolytic epidermal nevus caused by a somatic mosaic keratin mutation in *KRT1* or *KRT10*. Gonadal involvement of the keratin mutation, more common in those with widespread epidermal nevi, results in an offspring affected by generalized EI. Clinically, an epidermolytic epidermal nevus is indistinguishable from other types of epidermal nevi, but a biopsy would show features of EI. Prenatal diagnosis is possible if there is a known mutation (Chassaing et al., 2006).

Epidermolytic Ichthyosis

The 2009 classification scheme for ichthyosis proposed the term *keratinopathic ichthyosis* to encompass ichthyoses that are a result of keratin mutations, most of which are autosomal dominant. Epidermolytic ichthyosis (EI), previously referred to as *epidermolytic*

Diagnosis of Ichthyoses

Cutaneous and extracutaneous clinical features are critical in narrowing down the differential diagnosis for a neonate born with scaly or hyperkeratotic skin and can sometimes be sufficient for diagnosis. Family history may be helpful, particularly for ichthyoses

with a dominant inheritance pattern. The gold standard for diagnosis is genetic mutation analysis.

Histopathologic findings from a skin biopsy in many patients with ichthyosis are nonspecific, with a few exceptions. EI has characteristic histologic findings of “epidermolytic hyperkeratosis” discussed earlier. Biopsy specimens from an individual with ichthyosis vulgaris, NS, TTD, Refsum syndrome, or Conradi–Hünemann–Happle syndrome (chondrodysplasia punctata X-linked dominant type 2) may show reduced or absent stratum granulosum. Histopathology of loricrin keratoderma is notable for parakeratosis and hypergranulosis (Oji, 2010). Special immunohistochemical stains or ultrastructural analysis by electron microscopy may be considered in certain cases.

Examination of hair shafts can be helpful for diagnosing NS and TTD. Trichorrhexis invaginata (“bamboo hair” or “ball-and-socket” deformity) is characteristic of NS but is not usually present until after 1 year of age and even then is invariably present. The hair of patients with TTD may show trichoschisis (clean transverse fracture) or trichorrhexis nodosa (nodes from longitudinal splitting of fibers) on light microscopy and characteristic tiger-tail banding on polarized microscopy from low sulfur content.

Further work-up for syndromic ichthyoses is typically based on extracutaneous findings.

Prognosis and Treatment of Ichthyoses

Distinguishing the type of ichthyosis is crucial for offering prognostic information to the family, as prognosis is highly variable. Neonatal care for severe phenotypes, including collodion baby, LI, HI, and EI, was discussed earlier. For all types of ichthyosis, skin care typically involves application of bland emollients to hydrate the stratum corneum. Emollients with keratolytics such as urea, salicylic acid, α -hydroxy acids, and propylene glycol are usually avoided in infancy because of risk of toxicity from absorption. Oral retinoids are primarily considered for patients with HI or rarely in those with severe collodion membrane with delayed shedding.

Epidermolysis Bullosa

EB encompasses a group of mechanobullous disorders characterized by skin fragility and blister formation. The clinical spectrum is broad, but in the neonatal period most patients have vesicles, bullae, or erosions. Most forms of EB are caused by genetic mutations that result in absent or reduced levels of adhesion proteins normally present at the interface of the epidermis and dermis, which is called the *basement membrane zone* (BMZ). As a result, the epidermis separates from the dermis with less friction or force than usual, resulting in blister formation. In some EB subtypes, the epithelia of the external eye, ear, nose, upper airway, and gastrointestinal and genitourinary tracts are involved. The nature of the mutated protein and the severity of the mutation typically determine the phenotype: whether blistering is localized or generalized and the extent of extracutaneous involvement. As a general rule, less severe forms of EB tend to be more common and autosomal dominantly inherited, whereas more severe forms are rarer and autosomal recessive (Fine and Mellerio, 2009a; Gonzalez, 2013).

Classification of Epidermolysis Bullosa

EB classification and nomenclature have evolved over many years and were most recently updated at a 2013 international

consensus meeting (Fine et al., 2014). EB is classified into four major types: EB simplex, junctional EB, dystrophic EB, and Kindler syndrome. EB type is determined by the level of the skin at which mechanical fragility and blister formation occur. EB simplex is the most superficial form, with the level of skin cleavage occurring in the epidermis, usually in basal keratinocytes. In junctional EB, blisters form deeper, within the midportion (lamina lucida) of the skin's BMZ. Skin cleavage in dystrophic EB occurs just below the BMZ in the most superficial layer of the dermis (the sublamina densa). In Kindler syndrome, which is very rare, fragility and blister formation are seen at multiple depths within the skin. EB is further subdivided into more than 39 subtypes on the basis of clinical presentation, ultrastructural features, immunohistochemical findings, and the presence of specific genetic mutations (Fine et al., 2014). Only the more common or more notable subtypes are discussed in this chapter (Tables 104.5–104.8).

Epidermolysis Bullosa Simplex

EB simplex most commonly results from genetic mutations affecting keratins 5 and 14 in the basal layer of the epidermis (Table 104.5). Blisters typically heal without scarring. Most patients with EB simplex have autosomal dominantly inherited forms and a normal life span. However, some of the recessive forms, including those associated with muscular dystrophy and pyloric atresia, carry a poor prognosis and are associated with early death (Gonzalez, 2013). Patients with generalized subtypes of EB simplex (intermediate and severe types) present with blistering in the newborn period. Severe generalized EB simplex is characterized by extensive blistering in herpetiform (herpes-like) or arcuate clusters. Mucosal involvement may be seen, nail dystrophy is common, and progressive palmoplantar keratoderma is characteristic. In the intermediate subtype of generalized EB simplex, bullae are most common over pressure points such as the elbows, knees, legs, feet, and hands and may be widespread following the trauma of birth. Mucosal involvement may occur during the newborn period but reduces with age. Nails may be lost but regrow. Localized EB simplex is the most common form of EB. Patients with localized EB simplex are usually asymptomatic during the newborn period, with onset of acral blisters in early childhood.

Junctional Epidermolysis Bullosa

Junctional EB is caused by gene mutations that affect expression of proteins integral to the lamina lucida of the BMZ. All known subtypes of junctional EB are autosomal recessive, and clinical severity is highly variable (Table 104.6). Tooth enamel hypoplasia is characteristic. Generalized severe junctional EB, previously known as *Herlitz subtype*, is the most severe form and carries the highest risk of early death of all forms of EB (Fine et al., 2008). Patients present at birth with widespread mucosal and skin blistering, most pronounced over pressure points (Fig. 104.6). Nails are dystrophic or absent. Exuberant granulation tissue often develops periorally and on the upper back. Airway involvement is typical, and the eyes and gastrointestinal and genitourinary systems are also commonly affected. Prognosis is extremely poor. Most patients die during the first 2 years of life secondary to failure to thrive, sepsis, or respiratory failure (Gonzalez, 2013). The presentation of the generalized intermediate subtype of junctional EB is variable and less severe than that of the generalized form. Localized subtypes are also seen.

TABLE 104.5 Subtypes of Epidermolysis Bullosa Simplex

| Subtype and Previous Eponym | Inheritance | Gene(s)/Protein(s) | Clinical Features |
|--|-------------|--|--|
| EBS, generalized severe (EBS, Dowling–Meara) | AD | <i>KRT5</i> /keratin 5 <i>KRT14</i> /keratin 14 | Presentation: birth Bullae: herpetiform, generalized Mucosal involvement: present or absent Nails: dystrophic Prognosis: progressive PPK, blistering abates with age |

AR, Autosomal recessive; GI, gastrointestinal; GU, genitourinary; JEB, junctional epidermolysis bullosa.

Dystrophic Epidermolysis Bullosa

The dystrophic subtypes of EB are all caused by mutations affecting the expression of collagen VII, which forms the anchoring fibrils, critical for adhesion of the basement membrane to the upper dermis. Blistering occurs just below the BMZ, resulting in significant scarring and milia formation (Fig. 104.7). Dystrophic EB can be

categorized into autosomal dominant and recessive variants. In general, recessively inherited forms are associated with absence of collagen VII and are more severe than dominant forms, in which collagen VII expression is decreased or abnormal (Table 104.7).

The generalized severe recessive variant is the most severe subtype of dystrophic EB. Patients present at birth with generalized blistering of the skin and mucosa. Involvement of multiple organ systems,

TABLE 104.7 Dystrophic Epidermolysis Bullosa

| Subtype and Previous Eponym | Inheritance | Gene/Protein | Clinical Features |
|--|-------------|-----------------------------|--|
| RDEB, generalized severe (RDEB, Hallopeau–Siemens) | AR | <i>COL7A1</i> /collagen VII | Presentation: birth Blistering: widespread, involving skin and mucosa Nails: dystrophic or absent Extracutaneous involvement: ocular, GI tract, GU system, kidneys, heart Sequelae: mutilating scarring, pseudosyndactyly of digits, aggressive SCC Prognosis: poor, death most commonly caused by metastatic SCC |
| RDEB, generalized intermediate (RDEB, non-Hallopeau–Siemens) | AR | <i>COL7A1</i> /collagen VII | Presentation: birth Blistering: widespread but less severe involvement of skin and mucosa Nails: dystrophic or absent Extracutaneous involvement: variable to absent Sequelae: variable pseudosyndactyly, SCC Prognosis: lifelong blistering, risk of early death |
| DDEB, generalized (DDEB, Cockayne–Touraine, and Pasini) | AD | <i>COL7A1</i> /collagen VII | Presentation: birth Blistering: most pronounced on hands, feet, knees, and elbows Nails: dystrophic or absent Extracutaneous involvement: variable GI tract involvement Prognosis: lifelong blistering but normal life span |
| Bullous dermolysis of the newborn | AR, AD | <i>COL7A1</i> /collagen VII | Presentation: birth Blistering: generalized or localized; spontaneous or induced by trauma Prognosis: spontaneous resolution in first year of life |

AD, Autosomal dominant; *AR*, autosomal recessive; *DDEB*, dominant dystrophic epidermolysis bullosa; *GI* gastrointestinal; *GU*, genitourinary; *RDEB*, recessive dystrophic epidermolysis bullosa; *SCC*, squamous cell carcinoma.

TABLE 104.8 Kindler Syndrome

| Inheritance | Gene/Protein | Clinical Features |
|-------------|-------------------------|--|
| AR | <i>KIND1</i> /kindlin 1 | Presentation: birth Blistering: split at multiple levels of the skin; induced by trauma Marked photosensitivity and poikiloderma of sun-exposed skin Extracutaneous: gingivitis, colitis, mucosal stenosis, pseudosyndactyly Prognosis: blistering reduces and poikiloderma worsens with age; normal life span |

AR, Autosomal recessive

including the eyes, gastrointestinal tract, kidneys, genitourinary tract, and the heart, can be seen. Scarring of the hands and feet can lead to functionally limiting pseudosyndactyly and bone deformation. Anemia and failure to thrive are characteristic (Fine and Mellerio, 2009b). Aggressive squamous cell carcinomas arising in chronic wounds are the most common cause of death in patients with recessive dystrophic EB and develop as early as the teenage years (Fine et al., 2008).

• **Fig. 104.6** Newborn with junctional epidermolysis bullosa who exhibited bullae in the diaper area and other areas of friction.

In patients with dominantly inherited forms of dystrophic EB, blistering is typically induced by trauma and limited to the hands, feet, elbows, and knees. Scarring and milia formation occur but do not typically cause functional impairment. Nail dystrophy or loss is common and may be the only manifestation of disease. Life expectancy is usually normal (Gonzalez, 2013). There is a subtype of dystrophic EB called *bullous dermolysis of the newborn* where

• **Fig. 104.7** Four-month-old with dystrophic epidermolysis bullosa characterized by bullae, erosions, and milia.

• **Fig. 104.8** Bullous dermolysis of the newborn with absent skin on legs and feet.

skin fragility is usually transient and spontaneously resolves within the first year of life (Radkevich-Brown and Shwayder, 2013). These patients are often born with absent skin (aplasia cutis), especially on the lower extremities (Fig. 104.8).

Diagnosis of Epidermolysis Bullosa

The differential diagnosis for skin blisters or erosions in the neonate is broad but should include EB. Traumatic and infectious causes of blistering should be ruled out. A thorough history, including family history of blistering disorders, should be obtained. Physical examination findings are an unreliable indicator of EB type during the neonatal period, and discussion of long-term prognosis should be deferred until the subtype of EB is known.

Differentiation between the types of EB is usually done by specialized examination of a skin biopsy specimen and cannot be done by routine light microscopy of hematoxylin- and eosin-stained sections, which would show blister formation at the dermal-epidermal junction in most types of EB. Skin biopsy should be performed at the junction of a fresh blister and normal skin. Ideally, a blister is induced by the rubbing of a pencil eraser against the skin until erythema develops. The level of blister formation (i.e.,

intraepidermal, lamina lucida, or superficial dermis) can be determined by transmission electron microscopy (TEM) or immunofluorescence antigen mapping (IFM) of newly induced blisters. TEM allows detailed visualization of the epidermal-dermal junction to determine whether blister formation occurs superficial to, within, or deep to the BMZ. IFM uses monoclonal antibodies directed against proteins in the BMZ to help determine the level of split and in some cases will show decreased or absent expression of certain proteins mutated in EB. IFM is being increasingly used rather than TEM, but both should be performed by a laboratory experienced in performing these studies on patients with EB. Following TEM or IFM, genetic testing for specific mutations can provide molecular diagnosis of the EB subtype. Sometimes genotype-phenotype correlations are available for known mutations. A list of laboratories that provide testing for EB can be found at <http://www.ncbi.nlm.nih.gov/gtr/tests/>. Unfortunately, cost is still a barrier to routine genetic testing. In families with a known history of EB, methods of prenatal or preimplantation diagnosis can be considered.

Management of Epidermolysis Bullosa

While molecular treatments for EB are on the horizon, supportive measures remain the mainstay of therapy. A multidisciplinary approach is important, involving specialists in fields such as dermatology, surgery, gastroenterology, otolaryngology, dentistry, hematology/oncology, wound care, pain management, occupational and physical therapy, nutrition, and psychology (Fine and Mellerio, 2009b; El Hachem et al., 2014). EB patients who die in infancy and early childhood most often succumb to sepsis, followed by failure to thrive and respiratory failure. Those with severe subtypes of junctional EB are at markedly higher risk of early death (Fine et al., 2008), and in some patients it may be appropriate to emphasize comfort measures over aggressive treatments that prolong life (Yan et al., 2007).

In the neonatal period, prevention of new blisters and prevention of infection are of the utmost importance. Gentle handling and avoiding of frictional trauma should be emphasized. Infants should be rolled or moved with a sheet when possible to avoid friction. When lifting is necessary, one hand should gently support the head and neck, with the other under the buttocks. Ambient temperature should be cool, and routine use of incubators should be avoided, as heat may increase skin fragility. Bedding should be soft, and silicone dressings or padding should be applied to bony prominences and inside diapers. Intact bullae should be gently ruptured and drained with a sterile needle, leaving the roof intact as a biologic dressing. Wounds should be covered with nonadhesive dressings, and these should be changed daily or every other day. Tape and adhesives should never be applied to the skin. Nonadhesive wound dressings can be placed under pulse oximeter probes and electrocardiogram leads. Prevention of infection often involves use of chlorhexidine, dilute bleach, and/or dilute vinegar baths. Topical antibiotics should be used sparingly to avoid resistance. Pain control is essential (El Hachem et al., 2014).

Aggressive nutritional support is essential, especially in patients with feeding difficulties caused by significant mucosal involvement, or pyloric atresia, or those with increased fluid and energy requirements because of widespread blistering (El Hachem et al., 2014). Soft nipples used for feeding infants with cleft palates should be used in those with oral involvement. EB patients are prone to cutaneous infection, most commonly with *Staphylococcus*, which may disseminate. Indwelling catheters and overuse of topical

antibiotics such as mupirocin should be avoided when possible (Fine and Mellerio, 2009a). Tracheostomy may be indicated in patients with airway involvement (Yan et al., 2007; Fine and Mellerio, 2009b). Surgical repair of pyloric atresia enhances survival in affected patients, particularly those with relatively mild skin involvement (Fine and Mellerio, 2009b). Patients with severe disease should also be monitored for iron-deficiency anemia.

Incontinentia Pigmenti

Incontinentia pigmenti (IP), also referred to as *Bloch–Sulzberger syndrome*, is an X-linked neuroectodermal disorder that variably affects the skin, hair, nails, teeth, eyes, and central nervous system (CNS). The disorder is caused by mutations in the *IKBKG* gene, also called *NEMO* (which encodes nuclear factor κ B essential modulator), localized to chromosome band Xq28. The vast majority of patients with IP are female, suggesting causative mutations in *IKBKG* are lethal in males, but there are rare reports of affected males with Klinefelter syndrome (XXY genotype), somatic mosaicism, or hypomorphic alleles (Ardelean and Pope, 2006; Buinauskaitė et al., 2010). Females with a missense mutation in *IKBKG* may have a son with X-linked ectodermal dysplasia with immunodeficiency, discussed later in this chapter. Females with IP are functionally mosaic because of random X chromosome inactivation early in embryologic development (lyonization), which explains the variability in clinical phenotype. Cutaneous lesions of IP demonstrate mosaicism and typically follow Blaschko lines.

Cutaneous Findings

Almost all patients with IP will exhibit cutaneous features at birth or within the first few weeks of life. Four classic stages of skin lesions have been described, but not all patients will exhibit each stage, and there can be overlapping of stages. Stage 1 is characterized by erythema and vesiculobullous or pustular lesions in a linear and whorled pattern following Blaschko lines (Fig. 104.9). This stage can last from weeks to months and then resolves spontaneously but can recur even years later, often precipitated by infection. The distribution along Blaschko lines can help distinguish cutaneous lesions of IP from herpes or bacterial infection.

In stage 2 there are linear, hyperkeratotic, verrucous papules and plaques that may or may not have evolved from previous vesiculobullous lesions. The verrucous stage is usually distributed on the extremities and is most pronounced on the hands or feet. These lesions often resolve by about 6 months of age but rarely persist or recur.

Stage 3 is characterized by linear and whorled brown to slate-gray hyperpigmentation along Blaschko lines and typically involves both the trunk and extremities or just the trunk. The distribution does not usually correspond to prior inflammatory or verrucous lesions. This stage begins within the first few weeks to months of life and may last for years, often resolving spontaneously by adolescence or adulthood.

Less than half of patients exhibit stage 4, with atrophic, hypopigmented, or hypovascular streaks lacking adnexa (hair follicles or sweat glands). These are often located on the posterior lower extremities and may be subtle and thus underreported. The atrophic lesions are persistent and may be the only cutaneous finding in adulthood (Berlin et al., 2002).

Patients with IP may have variable alopecia (especially of vertex of scalp) and nail dystrophy.

Extracutaneous Findings

Dental anomalies are the most common extracutaneous manifestation of IP and may affect both deciduous and permanent teeth. Ocular abnormalities (both retinal and nonretinal) are highly variable but can be vision threatening and usually present by 1 to 2 years of age. CNS involvement is estimated to occur in about 30% of patients with IP and may include seizures, spastic paralysis, or developmental delay. Rare breast, cardiac, or skeletal abnormalities have been reported.

Diagnosis

The diagnosis of IP can often be made on the basis of clinical findings (Landy and Donnai, 1993) and confirmed by genetic testing for mutations in the *IKBKG* gene. A biopsy of cutaneous lesions in stage 1 will reveal characteristic infiltration of the epidermis by eosinophils with intraepidermal vesicles and dyskeratosis. Stage

• **Fig. 104.9** Newborn with incontinentia pigmenti who exhibited extensive vesiculobullous lesions on the trunk (A) and extremities (B), some following Blaschko lines.

1 may also be associated with a striking peripheral leukocytosis and eosinophilia. These findings can help differentiate vesiculobullous or pustular lesions of IP from infectious causes (such as herpes, varicella, or bullous impetigo), Langerhans cell histiocytosis, EB, autoimmune bullous diseases, bullous mastocytosis, or child abuse. Histopathology of stage 2 lesions shows papillomatosis, hyperkeratosis, and dyskeratosis; however, these same findings can be seen in epidermal nevi. Skin biopsy findings from stage 3 or stage 4 lesions are nonspecific.

Prognosis and Treatment

The cutaneous findings in IP, other than stage 4 atrophic or hypopigmented lesions, resolve spontaneously. Vesiculobullous lesions may require dressings or wound care, with monitoring for superinfection. All patients with suspected IP should have a thorough ophthalmology evaluation soon after birth. Careful neurologic examination is essential, and neuroimaging and electroencephalographic studies should be performed in patients with signs of CNS involvement. Dental evaluations should begin by age 2 years (Berlin et al., 2002).

Focal Dermal Hypoplasia (Goltz Syndrome)

Focal dermal hypoplasia, also known as *Goltz syndrome*, is a rare condition with skin, skeletal, ocular, and other manifestations. It is an X-linked dominant disorder caused by mutations in the *PORCN* gene and predominantly affects females (90%) as mutations are often lethal in males. Cutaneous lesions are usually present at birth, including linear streaks of dermal hypoplasia associated with telangiectasias or pigmentary changes that follow Blaschko lines, yellow to red-brown nodules or outpouching caused by herniation of fat through hypoplastic dermis, and ulcers caused by congenital absence of skin (aplasia cutis). Erythematous papillomas affecting the skin or mucosa may appear later. Nail hypoplasia or ridging, alopecia, and dental abnormalities are common. Skeletal manifestations include craniofacial findings and limb malformations such

as ectrodactyly or syndactyly. X-ray of long bones reveals longitudinal striations of the metaphyses (osteopathia striata). A number of developmental abnormalities of the eye have been associated with focal dermal hypoplasia. Other developmental anomalies, including congenital diaphragmatic hernia, have been described. Most individuals have normal development, but developmental delay has been reported. Treatment of affected individuals requires a multidisciplinary approach (Sutton and Van den Veyver, 2016; Bostwick et al., 2016).

Ehlers–Danlos Syndrome

Ehlers–Danlos syndrome (EDS) is a heterogeneous group of disorders with variable manifestations of cutaneous elasticity, joint hypermobility, and tissue fragility. The revised Villefranche classification from 1997 is still widely used (Table 104.9), but new variants and advances in molecular classification have since been described (Beighton et al., 1998; De Paepe and Malfait, 2012). Most forms of EDS are caused by mutations in genes encoding fibrillar collagens or enzymes that modify these collagens. Premature rupture of membranes is more common in infants with EDS or in pregnancies of affected mothers.

The most common type is classic EDS. These individuals have soft, velvety skin with a doughy texture that is hyperextensible but returns to the normal position after being stretched (in contrast to cutis laxa, discussed later) (Fig. 104.10A). The skin is also fragile with a tendency to form widened, atrophic scars often referred to as *fish-mouth* or *cigarette-paper scars*. Vessel fragility leads to easy bruising (see Fig. 104.10B). Hematomas can become fibrotic and may result in soft subcutaneous nodules referred to as *pseudotumors* or hard calcified nodules referred to as *spheroids*. Classic EDS is also characterized by joint hypermobility and resulting complications (Sobey, 2015).

The vascular type has the most severe prognosis as there is risk of life-threatening arterial or organ rupture. The cutaneous findings include thin, translucent skin and extensive bruising but not skin hyperextensibility. Joint hypermobility usually affects just the digits.

TABLE
104.9

Types of Ehlers–Danlos Syndrome in the Revised Villefranche Classification (Beighton et al., 1998)

| Type | Inheritance | Gene(s) | Cutaneous Features | Extracutaneous Features |
|-----------------|-------------|---|--|--|
| Classic | AD | <i>COL5A1</i> , <i>COL5A2</i> , <i>COL1A1</i> | Hyperextensibility, fragility, widened atrophic scars, easy bruising, pseudotumors, calcified subcutaneous nodules (spheroids) | Joint hypermobility |
| Hypermobile | AD | Unknown | Velvety skin, mild hyperextensibility | Joint hypermobility |
| Vascular | AD | <i>COL3A1</i> | Thin translucent skin, easy bruising, early varicosities, acrogeria (premature aged appearance) | Arterial dissection, aneurysm, and rupture; organ rupture; typical facies; pneumothoraces; joint hypermobility limited to digits |
| Kyphoscoliosis | AR | <i>PLOD1</i> | Hyperextensibility, fragility, widened atrophic scars, easy bruising | Congenital progressive kyphoscoliosis; hypotonia; gross motor delay; joint hypermobility; scleral fragility; vascular rupture |
| Arthrochalasia | AD | <i>COL1A1</i> , <i>COL1A2</i> | Hyperextensibility, with or without atrophic scars, easy bruising | Severe joint hypermobility; congenital bilateral hip dislocation; hypotonia; gross motor delay; dysmorphic features |
| Dermatosparaxis | AR | <i>ADAMTS2</i> | Severe fragility, redundant sagging skin | Congenital skull fractures; blue sclera; umbilical hernia; delayed fontanelle closure; short stature |

AD, Autosomal dominant; AR, autosomal recessive.

• **Fig. 104.10** Three-year-old girl with classic Ehlers-Danlos syndrome characterized by hyperextensible skin (A) and easy bruising (B).

Vascular EDS must be differentiated from other subtypes of EDS and Loeys-Dietz syndrome, an autosomal dominant condition caused by mutations in genes affecting transforming growth factor β signaling that is characterized by joint hypermobility, translucent velvety skin, and widespread vascular tortuosity with a high risk of aneurysms and dissections (MacCarrick et al., 2014).

The dermatosparaxis type is a very rare but severe phenotype that often presents at birth and has been associated with congenital skull fractures and skin lacerations (Solomons et al., 2013).

Cutis Laxa

Cutis laxa can be congenital or acquired. Inherited forms may be autosomal recessive, autosomal dominant, or X-linked, and mutations in at least nine different genes have been reported to cause variants of cutis laxa. The autosomal dominant form is caused by mutations in the *ELN* gene, which encodes elastin, and other genes that affect proteins involved in production of elastic fibers. The skin of patients with cutis laxa is characterized by loose, redundant, hypoelastic skin that does not recoil after stretching. The cutaneous findings are often evident at birth in autosomal recessive cutis laxa. Elastic fibers in extracutaneous sites can also be affected, resulting in varying clinical phenotypes depending on the genetic mutation (Berk et al., 2012).

The X-linked form of cutis laxa, once classified as a type of EDS, is also referred to as *occipital horn syndrome*. This disorder is caused by mutations in the *ATP7A* gene leading to impaired copper metabolism and is allelic with Menkes disease. Cutaneous manifestations of these allelic conditions may include soft, doughy skin and hypopigmented, fragile, kinky hair (pili torti).

Ectodermal Dysplasias

The ectodermal dysplasias comprise a heterogeneous group of more than 200 inherited conditions characterized by congenital defects in one or more ectodermal structures and appendages: hair, teeth, nails, and eccrine (sweat) glands. Many of these syndromes are associated with nonectodermal abnormalities (Itin, 2014; Pagnan and Visinoni, 2014). The classification of ectodermal dysplasias is evolving with elucidation of the genetics and molecular pathways

involved (Salinas et al., 2014). In 2009 a new classification scheme for ectodermal dysplasias broadly classified them into two groups on the basis of molecular data and clinical phenotype. Group 1 ectodermal dysplasias are caused by aberrant signaling between the ectoderm and mesenchyme, leading to abnormal tissue differentiation and development of ectodermal structures. The most common pathways affected are the tumor necrosis factor/tumor necrosis factor receptor and p63 pathways, and the most common phenotype is hypohidrotic ectodermal dysplasia (HED). In group 2 ectodermal dysplasias, differentiation of embryonic tissues is normal, and downstream defects in gene expression or transcription are the cause of ectodermal anomalies. The most common group 2 ectodermal dysplasia is Clouston syndrome (Paller, 2011).

Characteristic dysmorphic features and hypotrichosis are often the earliest recognized signs of ectodermal dysplasia. Temperature dysregulation is a common complication of hypohidrosis (reduced sweating) and may lead to recurrent fevers of unknown origin. The clinical features of the ectodermal dysplasias are diverse. The most common or notable forms are summarized in Table 104.10.

Hypohidrotic Ectodermal Dysplasia

HED is the most common type of ectodermal dysplasia and most often results from an X-linked recessive mutation of the ectodysplasin A gene (*EDA*). The classic triad of associated clinical features is hypohidrosis, alopecia, and hypodontia (reduced number of teeth). In X-linked HED, males are hemizygous for the *EDA* mutation and generally display the complete triad, as well as a propensity for respiratory disorders. Most are identified within the first 2 years of life. Females are typically heterozygous for the *EDA* mutation. Their presentation may be subtle and diagnosis delayed.

Infants with X-linked HED may exhibit failure to thrive, nasal congestion, decreased saliva production, and gastroesophageal reflux. Eczema usually presents during the first year of life. Males are more likely to suffer from respiratory problems, including chronic, malodorous nasal congestion, wheezing, and recurrent sinusitis (Fete et al., 2014).

HED with immunodeficiency (HED-ID) is most commonly caused by mutations in the *IKBKKG* gene on chromosome band Xq28. Female carriers of more severe mutations in this same gene

have IP, as discussed earlier. Patients with HED-ID usually present with recurrent infections.

Management of Ectodermal Dysplasias

Management of ectodermal dysplasia hinges on establishing the diagnosis, referral to appropriate specialists on the basis of symptoms

and known associations, and supportive measures. Early involvement of a geneticist is important, and ideally molecular confirmation of the diagnosis is obtained. For children with hypohidrotic forms of ectodermal dysplasia, avoidance of overheating is paramount. Eye drops and nasal irrigation should be used to lubricate the ocular and respiratory mucosa. Dental assessment should be performed early in life as intervention may be initiated before age

2 years. Ectodermal dysplasia associated with immunodeficiency may be treated with hematopoietic stem cell transplant, and more targeted molecular therapies may be available in the future (Paller, 2011).

Disorders With Generalized Hypopigmentation

Oculocutaneous albinism (OCA) is characterized by generalized hypopigmentation of the skin, hair, and eyes, with additional ocular abnormalities. OCAs are classified into “classic” nonsyndromic types and syndromic forms with additional systemic manifestations. There are seven identified forms of nonsyndromic OCA, each associated with a specific gene mutation. The implicated gene mutations affect proteins integral to melanin production or distribution. Severity of pigment loss and ocular manifestations differ depending on the OCA type and mutation severity. For example, the most severe type of OCA, OCA type 1A, is caused by a nonsense mutation in the tyrosinase gene, resulting in complete absence of melanin production. OCA type 1B is caused by a missense mutation in the same gene, allowing various amounts of melanin production. OCA types 1 to 4 account for most cases, and their pathogenesis and clinical features are summarized in Table 104.11 (Kamaraj, 2014).

Hermansky–Pudlak, Chédiak–Higashi, and Griscelli syndromes are syndromic forms of OCA. Hermansky–Pudlak syndrome is most commonly observed in the Puerto Rican population. In addition to OCA, patients have abnormal platelet function and are prone to bleeding. The intestines, lungs, kidneys, and heart may also be affected. Patients with Chédiak–Higashi syndrome

have impaired phagocytosis and are prone to pyogenic infections. Griscelli syndrome is associated with neurologic or immunologic abnormalities. Patients with metabolic disease may also present with generalized hypopigmentation. For example, those with Menkes disease are unable to metabolize copper and therefore lack this essential cofactor for tyrosinase activity and melanin production (Montoliu et al., 2014).

Diagnosis of Oculocutaneous Albinism

In patients with severe forms of OCA the diagnosis is often clinically apparent during the neonatal period. However, presentation may be subtle in patients with some melanin production, such as those with OCA types 2 and 3 born to darker-skinned parents. Comparison of skin, hair, and eye color with that of other family members may be helpful. Genetic testing performed at specialized centers currently identifies causative mutations in approximately 80% of OCA patients (Montoliu et al., 2014).

Treatment of Oculocutaneous Albinism

Treatment of OCA is geared toward addressing visual impairment and preventing sun-induced carcinogenesis. Early referral to and regular monitoring by an ophthalmologist is critical. Vigilant sun avoidance and protection, with use of sunscreen, UV-protective clothing, and eyewear, is essential. Sunscreens with physical blockers—namely, zinc oxide and titanium dioxide—are generally considered to be safest in infants and children. Clinical trials of medications designed to enhance melanin production in patients with albinism and related disorders are currently under way (Kamaraj, 2014).

TABLE 104.11 Congenital Disorders With Generalized Loss of Skin Pigmentation (Kamaraj and Purohit, 2014; Montoliu et al., 2014; Que et al., 2015)

| Syndrome | Pathogenesis | Clinical Features |
|---------------------------|---|--|
| OCA types 1A and 1B | AR mutation in the tyrosinase (<i>TYR</i>) gene, which codes for the key enzyme in melanin production | <ul style="list-style-type: none"> Most common OCA type in white Europeans Complete loss of (OCA type 1A) or significantly reduced (OCA type 1B) pigmentation: white or very light skin and hair Ocular: pink irides at birth become blue gray in adulthood, reduced visual acuity, strabismus, photophobia, nystagmus, misrouting of the optic nerves at the chiasm, foveal hypoplasia |
| OCA type 2 (brown OCA) | AR mutation in the <i>OCA2</i> gene, which codes for melanocyte-specific transporter protein, affecting melanin production and distribution | <ul style="list-style-type: none"> Most common OCA type in equatorial Africans Minimal to moderate skin pigmentation Hair white, golden, or red Irises translucent blue to light brown Ocular: similar to OCA type 1 |
| OCA type 3 (rufous OCA) | AR mutation in the <i>TYRP1</i> gene, leading to destabilization and compromised function of tyrosinase | <ul style="list-style-type: none"> Most common OCA type in southern Africans Skin red, freckled, or hypopigmented Reddish hair Light eyes Ocular: nystagmus, strabismus, positive red reflex Can be subtle: comparison with parents can aid in diagnosis |
| OCA type 4 | AR mutation in the <i>SLC24A5</i> gene, which may impair transport of substances integral to melanin synthesis | <ul style="list-style-type: none"> Most common in Japanese Light skin and hair Translucent irides Ocular: mild nystagmus and photophobia, decreased visual acuity, absent macula |
| Hermansky–Pudlak syndrome | AR mutation in the <i>HPS1</i> , <i>AP3B1</i> , <i>HPS3</i> , <i>HPS4</i> , <i>HPS5</i> , <i>HPS6</i> , <i>DTNBP1</i> , <i>BLOC1S3</i> , or <i>BLOC1S6</i> gene; these genes play a role in lysosome-related organelles | <ul style="list-style-type: none"> OCA, similar to OCA type 1 Abnormal platelets Easy bruising and bleeding Pulmonary fibrosis Cardiomyopathy Intestinal inflammation and hemorrhage Renal failure Most common in Puerto Ricans |
| Chédiak–Higashi syndrome | AR mutation in the <i>LYST</i> (<i>CHS1</i>) gene, which codes for lysosomal trafficking regulator protein, leading to defective lysosomal trafficking and phagocytosis | <ul style="list-style-type: none"> Variable skin hypopigmentation Ocular: similar to OCA type 3 Gingivitis Hepatosplenomegaly Recurrent pyogenic infections Progressive neurologic decline |
| Griselli syndrome | AR mutation in the <i>MYO5A</i> , <i>RAB27A</i> , or <i>MLPH</i> gene, leading to defective melanosome transport within melanocytes | <ul style="list-style-type: none"> Partial albinism, with hypopigmented skin, silver-gray hair Visual problems Neurologic impairment Immunodeficiency, hemophagocytic syndrome |
| Menkes disease | XLR mutation in the <i>ATP7A</i> gene (copper transporter), leading to impaired copper absorption and metabolism | <ul style="list-style-type: none"> “Doughy” inelastic, hypopigmented skin Hairs short, sparse, twisted (pili torti) Microcephaly, brachycephaly, pudgy cheeks Small stature Neurodegeneration: hypotonia, seizures, hypothermia Failure to thrive Impaired vision |

AD, Autosomal dominant; AR, autosomal recessive; OCA, oculocutaneous albinism; XLR, X-linked recessive.

Disorders With Localized Hypopigmentation

Piebaldism

Piebaldism is an autosomal dominant disorder characterized by circumscribed areas of leukoderma (absence of skin pigment). The anterior hairline is affected in 80%–90% of cases, resulting in a

white forelock (poliosis circumscripta) (Fig. 104.11A). This is frequently the sole manifestation (Grob and Grekin, 2016). Well-demarcated depigmented patches with islands of normal pigmentation and hyperpigmentation are typically present at birth and remain stable through adulthood (see Fig. 104.11B), although a few cases of spontaneous repigmentation have been reported (Frances et al., 2015). Characteristically, the ventral body is more affected,

• **Fig. 104.11** Father and son with piebaldism manifesting itself as white forelock (A) and well-demarcated depigmented patches with islands of normal pigmentation and hyperpigmentation (B).

particularly the central forehead, anterior trunk, arms, and legs. The dorsal midline, hands, feet, and periorificial regions are typically spared. Diagnosis is clinical and can be confirmed with molecular analysis of the *KIT* gene. Skin biopsy of depigmented areas is not necessary but when performed reveals absent or markedly reduced numbers of melanocytes. In the neonatal period, management of piebaldism hinges on vigilant photoprotection of amelanotic skin. Camouflaging makeup may be used for cosmetic purposes. Surgical and laser treatments are evolving and may be considered later in life.

The differential diagnosis for an infant with localized loss of skin or hair pigmentation includes disorders with systemic complications such as Waardenburg syndrome and tuberous sclerosis (Table 104.12) as well as nonsyndromic pigmentary anomalies. *Hypomelanosis of Ito* is a historical term used to describe linear and whorled hypopigmentation along Blaschko lines that may be an isolated cutaneous finding or associated with extracutaneous abnormalities, including neurologic or musculoskeletal conditions. Hypomelanosis of Ito is no longer considered a distinct entity but rather encompasses a group of disorders associated with various mosaic defects, and many prefer the term *pigmentary mosaicism* to describe the associated cutaneous findings. Other terms have been used to describe congenital hypopigmentation or depigmentation, including *patterned dyspigmentation*, *segmental pigmentation disorder*, and *nevus depigmentosus*. Congenital vitiligo has also been rarely reported. In any patient born with localized hypopigmentation or depigmentation, a thorough history, family history, and physical examination should be conducted, with further work-up directed by any abnormalities found (Lombillo and Sybert, 2005; Hogeling and Frieden, 2010).

Porphyrias

The porphyrias are a group of disorders caused by mutations in enzymes involved in heme biosynthesis that result in accumulation

of porphyrin or porphyrin precursors. Most porphyrias are autosomal dominant, but some are autosomal recessive, X-linked, or have more complex inheritance patterns. Cutaneous manifestations are due to the photosensitizing effects of porphyrins. Phototoxicity can be immediate with burning pain, erythema, and edema and/or delayed with blisters, dyspigmentation, and scarring. Traditionally, the porphyrias have been classified on the basis of the organ in which porphyrins or porphyrin precursors accumulate as erythropoietic (accumulation in bone marrow erythroid cells), hepatic (accumulation in liver), or mixed (i.e., hepatoerythropoietic porphyria). The porphyrias may be also categorized on the basis of primary symptoms, with “acute porphyrias” predominated by neurovisceral attacks and “cutaneous porphyrias” predominated by skin photosensitivity (Balwani and Desnick, 2012).

The erythropoietic porphyrias (congenital erythropoietic porphyria [CEP], erythropoietic protoporphyria [EPP], X-linked EPP [XLP]) and hepatoerythropoietic porphyria (HEP) can present in early infancy with severe photosensitivity and are reviewed in the following sections. Box 104.1 lists disorders that can present with photosensitivity in infancy. Phototherapy-induced eruptions because of transient porphyrinemia may be seen in neonates with hemolytic disease of the newborn (By et al., 2014; Villanueva et al., 2016).

The hepatic porphyrias are categorized by neurovisceral attacks, with variable cutaneous photosensitivity, and usually present later in childhood or adulthood. Exceptions include homozygous variants of hereditary coproporphyria, variegate porphyria, acute intermittent porphyria, and aminolevulinic acid dehydratase porphyria, which are exceedingly rare but can present in infancy.

Congenital Erythropoietic Porphyria

CEP, also known as *Günther disease*, is an autosomal recessive erythropoietic cutaneous porphyria caused by mutations in the gene encoding uroporphyrinogen III synthase. The disease is

TABLE 104.12**Syndromes With Congenital Localized Loss of Skin Pigmentation (Que et al., 2015; Grob and Grekin, 2016)**

| Syndrome | Pathogenesis | Clinical Features |
|----------------------|---|--|

AD, Autosomal dominant.

• BOX 104.1 Disorders That Present With Photosensitivity in Infancy

Porphyrrias
 Transient porphyrinemia
 Xeroderma pigmentosum
 Cockayne syndrome
 Bloom syndrome
 Rothmund–Thomson syndrome
 Smith–Lemli–Opitz syndrome
 Hartnup disease
 Neonatal lupus erythematosus
 Phototoxic or photoallergic reaction

characterized by severe photosensitivity and hemolytic anemia with splenomegaly. CEP may present in utero as nonimmune hydrops fetalis. Severe photosensitivity usually begins in infancy and can sometimes present in the neonatal period with blistering after phototherapy for hyperbilirubinemia. Scarring, hyperpigmentation, hypertrichosis, and disfigurement develop in photoexposed areas over time (Fig. 104.12). There are variable ocular manifestations. Urine may be faint pink to dark red from accumulation of uroporphyrin. The teeth also develop a reddish-brown color (erythrodonia). Teeth, urine, and stool may fluoresce under Wood lamp examination.

The diagnosis of CEP can be made on the basis of elevated uroporphyrin and coproporphyrin levels in erythrocytes, urine, and stool and can be confirmed by measurement of uroporphyrinogen III synthase activity or gene mutation analysis. Historically, CEP has been managed primarily with photoprotection and long-term transfusions. More recently, CEP has been cured with hematopoietic stem cell transplant, but transplant complications are not insignificant, including death, and thus may not be appropriate for all patients with CEP (Katugampola et al., 2012).

Erythropoietic Protoporphria and X-Linked Erythropoietic Protoporphria

EPP is the most common form of porphyria in childhood and is caused by autosomal recessive mutations in the gene encoding ferrochelatase. XLP, also referred to as *X-linked dominant protoporphyria*, is an X-linked form that results from mutations in the *ALAS2* gene, the product of which catalyzes the first committed step of heme biosynthesis (Whatley et al., 2008). XLP has a phenotype very similar to that of EPP but with higher concentrations of erythrocyte protoporphyrin and a higher incidence of liver disease (Seager et al., 2014).

Clinical manifestations of EPP include immediate painful photosensitivity to sunlight and sometimes fluorescent lighting. In infancy, this may manifest itself as episodes of crying within minutes of UV exposure, and older children may complain of stinging or a burning sensation in exposed areas. Prolonged exposure

• **Fig. 104.12** Two-year-old male with congenital erythropoietic porphyria who has bullae, crusted erosions, hyperpigmentation, and hypertrichosis in sun-exposed areas. He initially exhibited blistering after phototherapy for hyperbilirubinemia as a neonate.

may lead to erythema, edema, and petechiae and vary rarely vesicles or bullae. Long-term UV exposure results in shallow atrophic scars and thickened, leathery skin around the mouth (pseudorhagades) and overlying knuckles.

Hepatic involvement can range from mild liver dysfunction to rare liver failure. Cholelithiasis may cause severe abdominal pain. Anemia is usually mild or absent.

Diagnosis of EPP and XLP can be made on the basis of elevated erythrocyte protoporphyrin concentration, and red blood cells will fluoresce under Wood lamp examination. Increased stool protoporphyrin concentration may also be detected. The diagnosis is confirmed by genetic testing. Management in infancy includes sun avoidance and protection, with symptomatic treatment of photosensitivity reactions. Patients should be monitored for liver disease and microcytic anemia (Lecha et al., 2009; Balwani and Desnick, 2012).

Hepatoerythropoietic Porphyria

HEP is an exceedingly rare disorder caused by homozygous or compound heterozygous mutations in the gene encoding uroporphyrinogen decarboxylase. Heterozygous mutations or sporadic mutations in the same gene result in porphyria cutanea tarda, the most common porphyria in adults. HEP usually presents with severe bullous photosensitivity before age 2 years, with subsequent hypertrichosis and scarring, resembling CEP. The diagnosis can be made on the basis of highly elevated erythrocyte zinc protoporphyrin concentration, along with elevated urine and stool porphyrin concentrations, and can be confirmed by genetic testing (Liu et al., 2013).

KEY POINTS

- Owing to their cutaneous, immunologic, and renal immaturity, newborns (especially premature neonates) are at increased risk of infection.
- As a group of potentially life-threatening but often treatable diseases, infections must always be considered in a newborn with skin lesions.
- Prompt diagnosis and initiation of therapy are crucial to prevent devastating long-term sequelae, particularly in instances of disseminated disease.
- *Staphylococcus aureus*, *Streptococcus* species, *Candida albicans*, and herpes simplex virus are the most common causes of skin infections in the neonate.

Staphylococcus aureus Infections

Staphylococcus aureus is ubiquitous and harbored as a commensal organism in about one-third of the population, with a predilection for the nares (especially in children), perineum, and other moist cutaneous surfaces (Chen and Tsao, 2013). It is more likely to be present early if the child is born via cesarean delivery rather than vaginally, reflecting colonization via the bacterial microbiota of adult skin (Dominguez-Bello et al., 2010). However, by 1 week of age, most newborns will exhibit nasopharyngeal or umbilical colonization by *S. aureus*.

Invasive infection of infants by *S. aureus* remains a healthcare challenge. A retrospective study of staphylococcal infections in 348 neonatal intensive care units (NICUs) demonstrated that the incidence of invasive *S. aureus* infection (defined as a positive culture result from blood, cerebrospinal fluid [CSF], sterile fluid, or an abscess) was 44.8 per 10,000 infants. Most of these infections were caused by methicillin-sensitive strains (Ericson et al., 2015). Cutaneous signs of invasive *S. aureus* infection are mediated by local or circulating bacterial toxins; *S. aureus* is therefore responsible for skin lesions of protean morphology (Neylon et al., 2010).

Impetigo

Impetigo is a group of superficial skin infections caused by *S. aureus*, group A streptococcus (GAS), or both. Neonatal bullous impetigo is caused by *S. aureus* and can occur in nursery-based, epidemic patterns, often attributed to nasal carriage of *S. aureus*.

Clinical Findings

Impetigo is one of the most common neonatal skin infections. Bullous impetigo manifests itself as flaccid vesicles/bullae or pustules on an erythematous base, most often seen in the diaper area, periumbilically, or in skin folds (Fig. 105.1). Ruptured lesions leave behind a moist red base with a characteristic collarette of scale (Darmstadt and Lane, 1994; Hartman-Adams et al., 2014). Lesions of bullous impetigo are usually not closely grouped, which distinguishes this infection from herpes simplex virus (HSV) infection. Aggressive cases of *S. aureus* bullous impetigo may also present as widespread desquamation in a degloving pattern (Nguyen et al., 2016).

In contrast, nonbullous impetigo is characterized by thin-walled vesicles or pustules, often at sites of broken skin on the extremities or face. These lesions rapidly burst and assume their characteristic appearance of variably pruritic, eroded, red patches with a superimposed honey-colored crust. In both forms of impetigo, affected areas heal without scarring.

Etiology

S. aureus is the exclusive cause of bullous impetigo and the primary cause of nonbullous impetigo. GAS may also be associated with the nonbullous form. Bullous impetigo is mediated by local production of exfoliative toxin A (ETA) or B (ETB); these toxins cleave the desmosomal protein desmoglein 1 in the superficial layers of the epidermis. This loss of adhesion between keratinocytes results in characteristic flaccid blisters.

Diagnosis

Diagnosis is supported by the presence of gram-positive cocci in clusters on Gram stain of a swab from a pustule, vesicle, or crusted plaque of impetigo. Confirmation is made by bacterial culture taken from blood, skin, and soft tissues.

Treatment

Bullous impetigo is benign if treated early, although extensive local proliferation with exotoxin production or dissemination can be life threatening. Treatment should be instituted promptly and isolation maintained until lesions have ceased to spread, no longer have associated crusting, and have begun to reepithelialize. Infants should be closely monitored, and a high index of suspicion should be maintained for evidence of systemic disease. Infants with periumbilical lesions are at risk of bacterial omphalitis. Extremely limited infections may be treated with topical mupirocin, but this form of therapy should be used with caution in neonates. More extensive lesions require a systemically (most recommend

• **Fig. 105.1** Bullous Impetigo. Widespread superficial erosions with characteristic collarettes of scale in a periumbilical distribution.

parenterally) administered penicillinase-resistant antibiotic for 7 to 10 days. Antibiotic choice should ultimately be guided by sensitivities of cultured organisms, especially with the rising incidence of methicillin-resistant strains. In those cases, clindamycin, vancomycin, or linezolid would be considered.

Importantly, *S. aureus* outbreaks in nurseries continue to be documented, and it has been suggested that these epidemics may be underreported (Cimolai, 2003; Neylon et al., 2010; Paranthaman et al., 2014). These outbreaks may present as multiple cases of staphylococcal scalded skin syndrome (SSSS), pustulosis, bullous impetigo, abscesses, or other varied presentations of staphylococcal infection (Cimolai, 2003). Factors that have been proposed to increase the likelihood of staphylococcal outbreaks include crowded nurseries, poor adherence to hand washing by medical staff, inadequate umbilical cord care, nursery staff carriage of the organism, and lack of isolation early in the course of an outbreak. As such, universal hand-washing protocols, a reduction in overcrowding, increased nurse-to-patient ratio, and staff monitoring for carriage have all been proposed to mitigate the risk of nursery outbreaks. Aggressive monitoring of patients via active surveillance cultures and subsequent treatment of *S. aureus*-colonized neonates with topical mupirocin therapy and chlorhexidine baths have also been successful in limiting staphylococcal infections (Popoola et al., 2016).

Staphylococcal Scalded Skin Syndrome

In contrast to the localized effects of the exfoliative toxins that mediate bullous impetigo, SSSS is a generalized manifestation of circulating toxin produced by *S. aureus*. Early diagnosis and treatment of SSSS can be lifesaving.

Clinical Findings

SSSS is most common in full-term infants and young children, although cases of affected premature infants have also been reported

• **Fig. 105.2** Staphylococcal Scalded Skin Syndrome. Widespread erosions centered around the inguinal folds in a newborn. Note the diffuse background erythema.

(Kapoor et al., 2008; Arora et al., 2011). Affected infants demonstrate abrupt onset of temperature instability, lethargy, and irritability, with subsequent generalized skin tenderness and erythema. Initial erythema tends to occur on the face but subsequently becomes more marked in intertriginous areas (Li et al., 2014; Fig. 105.2). Facial swelling, conjunctivitis, and significant periorificial crusting is common; crusting accompanied by radial fissuring about the mouth gives afflicted children a characteristic appearance. Notably, mucosal surfaces are spared in SSSS. Following these initial signs and symptoms, focal or widespread flaccid bullae may develop within hours to days, with subsequent desquamation. This is easily elicited by light stroking of intact skin (Nikolsky sign). Following desquamation, affected areas appear as painful, shiny, denuded patches. At this stage, diffuse skin involvement may cause problems with thermoregulation, fluid and electrolyte balance, and superinfection (Neylon et al., 2010).

SSSS must be distinguished from toxic epidermal necrolysis (TEN), a life-threatening condition involving full-thickness epidermal necrosis, most commonly secondary to medication administration (Ladhani and Joannou, 2000). A distinguishing feature of these two conditions is the presence of mucosal blistering and hemorrhagic crusting in TEN.

Etiology

The signs and symptoms of SSSS are the result of circulating exfoliative toxins, produced from an often subclinical focus of *S. aureus* infection. Infants are thought to be more at risk of developing SSSS because of immunologic and renal immaturity, which allows excess accumulation of exfoliative toxin within the circulation. Specifically, significantly lower anti-exfoliative toxin antibodies have been noted in patients with SSSS compared with healthy controls (Saida et al., 2015). In contrast to bullous impetigo, which is more commonly associated with ETA, SSSS is more frequently

caused by ETB. Additionally, while *S. aureus* is identifiable in the blisters of bullous impetigo, in SSSS *S. aureus* is present at a primary distant site such as the nose, mouth, conjunctiva, umbilicus, or circumcision site. Fresh skin lesions are therefore sterile and blister fluid is culture negative.

Diagnosis

If the diagnosis is in question, a skin biopsy sample prepared for frozen section can be examined emergently. The presence of an intraepidermal rather than a full-thickness blister with separation at the dermal–epidermal junction distinguishes SSSS from TEN, allowing rapid initiation of appropriate therapy. If the clinical impression is strong, swabs from potential niduses of infection (nasopharynx, conjunctiva, umbilicus, etc.) may identify the primary focus. Gram staining may be performed emergently, while bacterial culture will confirm the diagnosis. Bullous lesions do not contain organisms. Blood culture specimens should be obtained because sepsis, although uncommon, may occur.

Treatment

Systemic administration of a penicillinase-resistant penicillin such as oxacillin is the treatment of choice, although other agents, such as clindamycin, may be considered. Clindamycin is a useful first-line agent for treatment of SSSS because of its superior cutaneous penetration, as well as its ability to inhibit bacterial toxin production. Nevertheless, reports assessing antibiotic resistance in SSSS have shown that there are certain geographic areas in which clindamycin-resistant strains predominate. As such, empiric treatment with both oxacillin and clindamycin may be useful until antibiotic sensitivities return (Braunstein et al., 2014). In cases of widespread disease, fluid and nutritional support and maintenance of normal body temperature may be required. Close monitoring for secondary superinfection (particularly with gram-negative organisms) is also warranted. Approximately 2 to 3 days after initiation of therapy, denuded areas become dry and desquamation ensues. Crusted, flaky areas may be treated with normal saline compresses. Application of a bland ointment emollient may promote skin healing and resolution. Additional treatment of family members may be considered in instances of recurrent staphylococcal skin infections. As in bullous impetigo, the intraepidermal cleavage plane is superficial and therefore does not result in scarring in the absence of secondary infection or other complications.

Streptococcus Species Infections

Cutaneous streptococcal infections occur in the newborn but are less common than staphylococcal infections. Nevertheless, outbreaks of GAS in nurseries have been reported (Nelson et al., 1976; Lehtonen et al., 1987), following introduction of the organism via maternal carriers or nursery personnel. Omphalitis is a common manifestation, although cellulitis, pustular eruptions, and paronychia may also be seen. GAS dissemination may occur and often presents as respiratory distress, a toxic shock–like syndrome, lethargy, abdominal distension, and poor oral intake (Miyairi et al., 2004). However, certain classic signs of invasive disease, such as fever, may not be present, particularly in neonates less than 5 days old. Meningitis is more commonly seen in affected individuals 5 days of age or older. Since sepsis and meningitis can result, infected infants should be identified and treated promptly, with strict isolation. Disinfection of the umbilical stump reservoir, and penicillin prophylaxis for carriers and exposed infants, have been the most

effective measures in preventing spread. Active GAS infections respond readily to penicillin.

Group B streptococcus (GBS) is now one of the most frequently encountered pathogens in the newborn nursery and is a primary cause of neonatal sepsis. Early-onset disease (during the first week of life), probably acquired during labor and delivery, most commonly becomes manifest as septicemia with respiratory distress and shock. Late-onset disease (7 days to 3 months) is acquired after birth and is more commonly associated with meningitis and adverse neurodevelopmental outcomes (Oh, 2013).

Skin infections caused by GBS are uncommon but have been documented. The most common skin manifestation of GBS is cellulitis, often of the face and neck (Albanyan and Baker, 1998; Strunk and Burgner, 2015). This so-called GBS cellulitis–adenitis syndrome typically occurs from 1 to 11 weeks of age and is characterized by progressive erythema and swelling. Extracutaneous symptoms include fever, irritability, and poor oral intake. Erosions, abscesses, and necrotizing fasciitis have also been noted with GBS. A diagnosis of GBS can be made via blood culture, which is often positive; CSF cultures are also recommended. Penicillin G or ampicillin is effective as first-line therapy.

Omphalitis

Omphalitis is a bacterial infection of the umbilical stump that presents around day 3 of life. It is commonly caused by *S. aureus*, *Staphylococcus epidermidis*, *Streptococcus* species (spp.), *Escherichia coli*, *Clostridium difficile*, *Klebsiella*, and *Pseudomonas*. Outbreaks in nurseries have been described and are often attributable to staphylococcal or streptococcal infections. Risk factors for the development of omphalitis include prematurity, low birth weight, umbilical cord catheterization, prolonged rupture of membranes, and perinatal maternal infection (Fraser et al., 2006).

Clinical Findings

Omphalitis is characterized by edema, erythema, and tenderness around the umbilicus. Purulent discharge may be present. Infection can evolve to cellulitis or lymphangitis or extend deeper into the subcutis or along the abdominal wall, causing necrotizing fasciitis. Other potential complications include sepsis, peritonitis, abscesses, and hepatic vein thrombosis.

Diagnosis

Gram stain and bacterial culture from moist umbilical stump fluid can be performed, but because this area can be contaminated easily, clinical correlation is needed. Infection must be differentiated from embryonic duct remnants.

Treatment

Systemically acting ampicillin and gentamicin can be used empirically to treat both gram-positive and gram-negative organisms until culture and sensitivities are obtained. Intravenous antibiotics can be switched to enteral antibiotics once the skin improves clinically. A Cochrane review analyzing the use of chlorhexidine antiseptic solution in the prevention of omphalitis indicated that cleansing of the umbilical cord with chlorhexidine, when compared with dry umbilical cord care, likely reduces the incidence of omphalitis and infections in the hospital setting, although it has no impact on infant mortality. In contrast, this practice does cause

reductions in omphalitis, infection, and mortality when used in the community setting (Sinha et al., 2015).

Candida Species Infections

Candida albicans is a yeast species that typically exists with humans as a commensal organism. Colonization of the gastrointestinal, respiratory, and cutaneous surfaces occurs rapidly after birth and is thought to occur primarily via the maternal genitourinary tract, although skin contact may contribute. Nevertheless, decreased host immunity, altered surface microbiota, and epidermal immaturity all contribute to *Candida* pathogenesis and invasive disease (Hube, 2004; Kelly et al., 2015). Development of active infection may occur in utero, during delivery, or postnatally.

Localized Candida Infection (Primary Cutaneous)

Oral Candidiasis (Thrush)

Oropharyngeal candidiasis is characterized by adherent white patches on a normal or erythematous base, most typically on the buccal mucosa or the tongue. These patches are characteristically recalcitrant to physical removal and may be asymptomatic or cause discomfort, resulting in decreased oral intake (Rowen, 2003). Although the peak incidence of *C. albicans* colonization of the oropharynx is estimated to occur at 4 weeks of age (Russell and Lay, 1973), most of the infants affected do not subsequently develop oral thrush. In a study of 650 infants in a NICU in India, however, approximately 3% developed symptomatic oral candidiasis at a mean age of 10.5 days, with birth asphyxia noted to be the only significant risk factor for this occurrence (Gupta et al., 1996). A more recent prospective study evaluating oral lesions of Turkish children in an outpatient setting found a 13.6% incidence of oral candidiasis in neonates less than 1 month of age (Yilmaz et al., 2011). Notably, thrush is more common in neonates born to mothers with symptomatic *Candida* vulvovaginitis rather than those who are simply colonized.

Candida Diaper Dermatitis

Candida diaper dermatitis is exceedingly common. Cutaneous candidiasis is characterized by widespread, confluent erythema with scalloped edges and characteristic involvement of moist, intertriginous areas. Peripheral white scale and satellite papules or pustules may be evident (Rowen, 2003). Alternatively, candidiasis may present as multiple pink papules with overlying scale that merge into broader plaques. In addition to the diaper area, intertriginous sites including the neck folds and axillae may also be infected with *Candida*, as may the nails.

Diagnosis of Localized Cutaneous Candida Infection

Presumptive diagnosis can be made by physical examination and history, but microscopic examination of scrapings suspended in 10% potassium hydroxide for yeast and pseudohyphae is useful. The diagnosis may be confirmed by identification of the organism in culture.

Treatment

Nystatin is a polyene antifungal with activity against *Candida* but not dermatophytes. Oral lesions usually respond promptly to a course of nystatin suspension, 100,000 to 200,000 units, administered by mouth four times daily for 14 to 21 days. In refractory

cases an increased dosage of nystatin or systemic therapy may be instituted (Hebert and Esterly, 1986). Orally or intravenously administered fluconazole has also been used for the treatment of recalcitrant oral thrush or in infants at high risk of dissemination. Nevertheless, its higher relative cost makes it a less suitable first-line treatment.

Localized cutaneous candidiasis in an otherwise healthy infant is most easily treated with topical agents, including nystatin, an imidazole antifungal (e.g., miconazole, ketoconazole), or ciclopirox olamine (Gibney and Siegfried, 1995). A recent study examining the efficacy of a 7-day course of 0.25% miconazole nitrate ointment in the treatment of diaper candidiasis showed a clinical cure rate of approximately 50%; cure rates for recurrent episodes were even higher and did not result in antifungal resistance (Blanco and van Rossem, 2013). Importantly, if a breastfeeding mother is also affected, treatment of the mother with nystatin cream or orally administered fluconazole may be indicated. Gentian (crystal) violet is an antiseptic dye effective against *Candida* species. In a 0.5% or 1% aqueous solution, it has proven to be a safe and effective treatment for thrush but is less commonly used because of side effects, including transient purple staining of the skin and mucosal ulceration. Carcinogenicity in mice has been reported.

Congenital (Intrauterine) Candidiasis

Congenital candidiasis refers to widespread candidiasis (rarely with extracutaneous involvement) that results from ascending intrauterine infection where *Candida* spp. cross the fetal membrane and infect surfaces that contact amniotic fluid. Congenital candidiasis occurs within 6 days after birth, although it is most commonly evident on the first day of life.

Clinical Findings

Lesions of congenital candidiasis may at times be seen on the placenta and fetal membranes, including characteristic miliary granulomas of the umbilical cord (Hebert and Esterly, 1986). These umbilical cord lesions are discrete yellow-white flat-topped papules, measuring 0.5 to 4 mm in diameter. Congenital cutaneous candidiasis (CCC) in affected infants is characterized by erythematous macules, papules, and vesicopustules with intense background erythema, often in various stages of development. The back, extensor extremities, and intertriginous areas are most commonly affected, while the face, oral mucosa, and diaper area are comparatively spared. Palmar and plantar pustules, paronychia, and nail involvement help distinguish this condition from more common, benign neonatal dermatoses (Darmstadt et al., 2000). A scald-like erythema reminiscent of disseminated neonatal candidiasis (see later) has also been reported in full-term infants but is more characteristic of CCC presenting in premature neonates with a birth weight below 1000 g (Darmstadt et al., 2000; Tieu et al., 2012). Skin lesions usually resolve with desquamation within 1 to 2 weeks, and nail changes improve spontaneously with time. The prognosis is good in full-term infants, but that of affected low-birth-weight infants is guarded (Gibney and Siegfried, 1995).

Diagnosis

The differential diagnosis for CCC is broad and includes other vesicopustular conditions (Box 105.1). Rapid bedside diagnosis can be made via a potassium hydroxide preparation that reveals budding yeasts and pseudohyphae. Positive results on cultures from an intact pustule or skin scrapings, as well as evidence of fungal elements present in the stratum corneum on histologic

- Langerhans cell histiocytosis

analysis of skin biopsy tissue, are also diagnostic. Cultures of skin, blood, urine, and CSF are usually negative; however, they are indicated when systemic disease is clinically suspected, as well as in all preterm infants.

Treatment

In full-term infants with an uncomplicated course, active nonintervention with close monitoring may be sufficient, as CCC resolves spontaneously within 1 to 2 weeks (Tieu et al., 2012). Alternatively, topical antifungals may be considered. In low-birth-weight infants, systemic treatment with amphotericin B should be considered (Johnson et al., 1981). Other risk factors that may warrant systemic treatment of at-risk neonates include antibiotic or corticosteroid therapy, indwelling catheters, and parenteral nutrition. Clinical findings including respiratory distress, widespread burn-like dermatitis, or other signs or symptoms of systemic infection also warrant more aggressive therapy.

Disseminated/Invasive Candidiasis

In contrast to congenital candidiasis, invasive candidiasis (IC) is a disseminated form of neonatal candidiasis characterized by *Candida* infection in otherwise sterile body fluid such as blood, urine, or CSF. It is more commonly seen in premature, very low-birth-weight (VLBW) infants, and is typically acquired via the vaginal canal or handling in the nursery, although congenital onset may also occur. In contrast to congenital candidiasis, invasive neonatal candidiasis usually presents after the first week of life. While IC is uncommon in infants weighing more than 2500 g, its incidence increases to 5%–10% in neonates weighing less than 1000 g. The most common causes of IC are *C. albicans* and *C. parapsilosis* species (Smith et al., 2005).

The risk factors for systemic infection include VLBW (less than 1500 g), indwelling catheters, endotracheal tubes, broad-spectrum antibiotic therapy (most specifically with third-generation cephalosporins), steroid administration, and parenteral nutrition with intravenous lipid emulsions (Benjamin et al., 2010). Infection rates differ across medical centers, owing to differences in the aforementioned modifiable risk factors. Mortality is estimated at approximately 20%–30% across all affected neonates, with even greater rates of accompanying morbidity in survivors (Benjamin et al., 2010; Greenberg and Benjamin, 2014).

Clinical Findings

Skin manifestations include erosive, burn-like dermatitis followed by desquamation, scaly and erythematous patches, papules, pustules, and abscesses (Fig. 105.3). Intertriginous accentuation and

• **Fig. 105.3** Congenital Candidiasis. “Sunburn-like” erythema with accompanying superficial desquamation on the back of a neonate.

involvement of the oral mucosa is often appreciated (Tieu et al., 2012). Systemic involvement occurs via hematogenous spread from gastrointestinal and cutaneous reservoirs, most frequently involving the kidney, central nervous system (CNS), and eyes. The spleen, liver, heart, bones, and joints may also be affected. Respiratory distress, temperature instability, apnea, bradycardia, abdominal distension, and hypotension are suggestive of IC and should prompt a thorough evaluation. Supportive laboratory features may include an elevated white blood cell count and thrombocytopenia, as well as persistent hyperglycemia and glycosuria (Smith et al., 2005).

Diagnosis

The differential diagnosis of IC with cutaneous involvement is similar to that for CCC and includes neonatal vesiculopustular eruptions that range from benign, self-limited cutaneous processes to rapidly progressive, life-threatening disease (Box 105.1). Early and correct diagnosis is essential. Organisms from skin are usually demonstrable on potassium hydroxide or calcofluor white preparations and cultures of scrapings from involved skin. The diagnosis of disseminated candidiasis can be expedited by a positive touch preparation of a punch biopsy specimen of skin. Using this technique, the practitioner firmly imprints the dermal side of the specimen on a microscope slide and then assesses it for yeast after potassium hydroxide preparation or Gram staining. Histologic examination of specimens from the placenta and umbilical cord prepared with the appropriate stains may also be supportive if fungal elements are demonstrated.

Disseminated disease can be difficult to diagnose, as culture of the organism from blood or CSF is estimated to have a sensitivity of 50% or less, and fungal antigen detection systems appear to have low sensitivity (and have also not been tested in neonates) (Smith et al., 2005; Greenberg and Benjamin, 2014). Although urine culture often leads to false-positive results, such findings are strongly associated with systemic disease in infants at risk and should be interpreted in the clinical context. In addition to blood, urine, and CSF cultures, ophthalmologic examination, chest x-ray for pulmonary involvement, echocardiogram, and head and abdominal ultrasonography should be considered.

Prognosis and Treatment

Systemic infection with *C. albicans* in premature infants is a serious infection with high morbidity and mortality. Sequelae of IC include neurodevelopmental impairment, deafness, retinopathy of prematurity, chronic lung disease, and renal failure (Smith et al., 2005; Barton et al., 2014). Minimizing the aforementioned risk factors for IC and instituting meticulous hand hygiene are considered effective means of prevention. Probiotic supplementation has also been posited to provide protection against IC (Kumar and Singhi, 2016). Empiric first-line treatment should be initiated while diagnostic results are awaited in patients for whom suspicion of IC is high, as this results in improved clinical outcomes. Among the various antifungals used to treat IC, fluconazole and amphotericin B are the agents of choice (including liposomal amphotericin B if urinary tract involvement is excluded) (Pappas et al., 2009; Greenberg and Benjamin, 2014). Echinocandins such as caspofungin are less favored but may also be considered, although they are inappropriate for cases with ophthalmologic involvement as they are unable to penetrate the vitreous. Fluconazole prophylaxis has been recommended for neonates weighing less than 1000 g cared for in NICUs with high rates of IC ($\geq 15\%$). However, a randomized controlled trial, evaluating the effects of fluconazole prophylaxis in patients weighing less than 750 g in NICUs with lower rates of IC (including most of those in the United States and European Union), showed no reduction in the rates of IC or death, suggesting that universal administration of fluconazole prophylaxis in this population may not be appropriate (Benjamin et al., 2014). Therapy is recommended for 21 days after microbiologic clearance as documented by culture and imaging.

Primary Cutaneous Aspergillosis

Primary cutaneous aspergillosis (PCA) is an increasingly common cutaneous infection in neonates, particularly the premature. This increased incidence is due in part to improved survival of extremely premature infants, as well as increased exposure to fungal spores made airborne by construction in and around hospitals (Vonberg and Gastmeier, 2006). PCA is thought to occur primarily via traumatic insult, with subsequent inoculation through intravenous line placement or use of adhesive tape, elastic dressings, armboards, or contaminated gauze. Contributing factors also include an immature skin barrier and immune system, frequent use of systemic corticosteroids in NICU patients, and administration of broad-spectrum antibiotics (Woodruff and Hebert, 2002; Simpson et al., 2015).

Clinical Findings

PCA typically presents as an erythematous papule, patch, or plaque that with time can become pustular and may eventuate in cutaneous ulceration with crusting and, at times, purpura (Fig. 105.4). The differential diagnosis for PCA includes other deep fungal infections, as well as cutaneous *Pseudomonas* infection or inflammatory conditions, including cutaneous polyarteritis nodosa or pyoderma gangrenosum (Woodruff and Hebert, 2002).

Diagnosis and Treatment

A diagnosis of PCA is made via skin biopsy for histologic analysis and tissue culture. Systemic involvement must also be excluded, particularly when lesions are multifocal. Specific evaluation including

• **Fig. 105.4** Primary Cutaneous Aspergillosis. Erythematous plaques and broad pustules, many with dusky centers, on the back of a premature neonate.

blood culture, chest x-ray, echocardiogram, funduscopic examination, lumbar puncture, and abdominal ultrasonography should be considered when one is evaluating a patient with known or suspected PCA.

The treatment of choice for PCA is amphotericin B, with consideration of use of its liposomal formulation. Voriconazole may be used as an alternative. For single lesions, surgical debridement should be considered to prevent systemic dissemination (Woodruff and Hebert, 2002; Simpson et al., 2015).

Tinea Capitis and Tinea Corporis

Although uncommon in neonates, dermatophytoses such as tinea corporis and tinea capitis are important infections to recognize as they can be clinically mistaken for more serious disorders. Most commonly caused by superficial invasion of the epidermis by *Trichophyton* and *Microsporum* species, dermatophytoses are thought to occur in infants in part because of epidermal and immune immaturity. Other predisposing factors in hospitalized infants (particularly in the NICU setting) include moist, humid environments, administration of broad-spectrum antibiotics, and frequent application of tapes and instrumentation (Atanasovski et al., 2011).

Clinical Findings

Clinically, neonatal tinea capitis presents with a variable combination of alopecia, erythema, and scale. An annular morphology may be appreciated, and lymphadenopathy may also be present. It may or may not be accompanied by tinea corporis (dermatophytosis of the body), which classically appears as an annular patch or thin plaque with central clearing and peripheral erythema and scale (Gilaberte et al., 2004; Fig. 105.5). Other more atypical presentations reported include pustules, nodules, and vesicles (Battin and Wilson, 2005). As such, the differential diagnosis for neonatal tinea includes neonatal lupus, Langerhans cell histiocytosis, impetigo, HSV infection, and benign diagnoses including seborrheic dermatitis.

Diagnosis and Treatment

Consideration of dermatophyte infection in the neonate is important as recognition of this infection can prevent costly, unnecessary

• **Fig. 105.5** Tinea Corporis. Annular erythema with central clearing on the forehead of an infant. Note the presence of erythematous papules and superficial scale on the periphery of the lesion.

procedures and evaluations to exclude more serious diagnoses, including neonatal lupus. Potassium hydroxide preparations are a useful bedside diagnostic tool to quickly diagnose tinea corporis or tinea capitis, while dermatophyte culture and skin biopsy may also be considered in more atypical presentations.

Treatment consists of either topical or oral antifungal therapy. Topical therapy two or three times daily with agents including azoles or terbinafine can help clear even scalp infections in neonates and is an appropriate first treatment choice as the risk of systemic absorption and potential side effects is low.

Herpes Simplex Virus Infection

HSV exists as two viral types, HSV-1 and HSV-2. Historically, HSV-2 was associated with genital eruptions, while HSV-1 was associated with orolabial infections, although the incidence of HSV-1-associated genital herpes appears to be increasing (James and Kimberlin, 2015). Neonatal infection can be associated with either serotype. Despite a high prevalence of HSV infections in adults, neonatal herpes is relatively uncommon. Nevertheless, early recognition and prompt initiation of therapy for neonatal herpes are critical, as the consequences of delaying therapy can be devastating. While approximately 5% of cases of HSV infection in the neonatal period are due to in utero exposure, with another 10% occurring after birth, most occur in the perinatal period.

Clinical Findings

Neonatal HSV infection is classified on the basis of the extent of involvement: skin, eye, and/or mouth (SEM) disease; CNS disease; or disseminated disease. Infection typically presents within the first week to 2 weeks after birth, with a slightly later onset of CNS disease at approximately 16 to 17 days. Neonatal HSV infection may present with temperature instability, lethargy, irritability, or poor oral intake or with a sepsis-like syndrome that may include new-onset seizures, pneumonia, and disseminated intravascular coagulation. Approximately 60% to 80% of afflicted neonates exhibit characteristic skin lesions or develop them during the course of the disease. Nevertheless, there remains a significant proportion

• **Fig. 105.6** Congenital Herpes Simplex Virus Infection. Broad ulceration with peripheral vesiculation and desquamation on the left arm of a neonate. (Photo courtesy of Albert Yan, MD; The Children's Hospital of Philadelphia, Philadelphia, PA, USA.)

of patients who never develop skin vesicles throughout their disease course (Kimberlin et al., 2001a; James and Kimberlin, 2015).

Approximately 45% of infected infants exhibit SEM disease. Characteristic cutaneous lesions begin as erythema that quickly evolves into isolated or grouped vesicles on an erythematous base. Continued evolution may result in pustules, crusts, or erosions. Vesiculation typically occurs at sites of trauma, including the presenting part and sites of fetal electrode placement (Arvin and Prober, 1992). Conjunctivitis is relatively common in SEM disease, although oral involvement remains rare. With early institution of therapy, infants with SEM disease have an excellent prognosis, with low rates of morbidity and a mortality rate of zero. Nevertheless, if infection is left untreated, it will progress to disseminated or CNS disease in three-quarters of all cases (Arvin and Prober, 1992). Additionally, infants with SEM disease and three or more recurrences of cutaneous vesicles in the first 6 months of life appear to be at greater risk of neurologic impairment (Kimberlin et al., 2011).

In contrast, approximately 30% of infected infants have CNS disease, with an increased associated mortality and risk of neurodevelopmental abnormalities. Prematurity and the presence of seizures at onset of therapy appear to portend a worse prognosis in infants with CNS disease, even with therapy (acyclovir era). The remaining 25% of infants have evidence of disseminated disease (sepsis, liver failure, encephalitis, disseminated intravascular coagulation, respiratory distress). Forty percent of patients in this group do not manifest any cutaneous findings (Pinninti and Kimberlin, 2014a). The prognosis of disseminated disease is worse than for other forms of neonatal HSV infection; treatment with high-dose acyclovir has improved outcomes compared with historical measures, but mortality associated with disseminated disease is still estimated at approximately 30%. Almost 20% of survivors have neurodevelopmental delays.

Infants infected in utero (congenital HSV infection) have a distinct clinical presentation (Fig. 105.6). Skin lesions are almost always present at birth and include widespread erosions and bullae, scars, hyperpigmentation, hypopigmentation, and aplasia cutis. Other frequent findings include microcephaly, hydranencephaly, intracranial calcification, chorioretinitis, optic atrophy, and microphthalmia (Arvin and Prober, 1992; James and Kimberlin, 2015).

Etiology

Most cases of neonatal herpes simplex are the result of vertical transmission in the perinatal period. Most cases of neonatal HSV infection in developed countries are secondary to HSV-1 infection, reflecting the increased prevalence of HSV-1 associated with genital herpes. The usual route of infection is via intrapartum contact with genital mucosa during a phase of active viral shedding, which may be symptomatic or asymptomatic. Nevertheless, physicians should also be aware of uncommon means of HSV transmission associated with certain ethnic or religious groups. For instance, postnatal transmission of HSV has been reported in ultra-orthodox Jewish populations in which orogenital suctioning of blood is performed following ritual circumcision (Tzvi-Behr et al., 2016).

Epidemiology

In developed countries, the incidence of neonatal HSV infection ranges from 1.6 to 33 per 100,000 live births (Pinninti and Kimberlin, 2014a). When compared with the risk of genital herpes reactivation, the risk of neonatal herpes is greater with maternal first episode primary or first episode nonprimary infection (the latter category reflects acquisition of an HSV serotype in individuals with preexisting protective antibodies versus the other serotype) (Brown et al., 2003). Unfortunately, it has been estimated that up to 80% of mothers who transmit HSV to their infants have no known history of genital herpes (James and Kimberlin, 2015). Vaginal delivery, prolonged rupture of membranes, and maternal infection with HSV-1 are additional risk factors for acquisition of HSV in the neonate.

Diagnosis

A high index of suspicion is required, particularly in cases without cutaneous manifestations. When characteristic herpetic lesions are present, the differential diagnosis includes other causes of vesicopustular eruptions (Box 105.1). A Tzanck smear test or direct fluorescent antibody detection using skin scrapings from the base of a fresh vesicle is a relatively rapid means of detecting cutaneous HSV infection, but the diagnostic yield of both is variable, largely influenced by the age, quality, and handling of the specimen. Viral culture and polymerase chain reaction (PCR) for HSV DNA are the preferred methods for diagnosing neonatal HSV infection; the sensitivity of PCR in identifying HSV DNA in CSF samples is 75% to 100% (Pinninti and Kimberlin, 2014a). Obtaining specimens from the CSF, oropharynx, anus, conjunctivae, and nasopharynx is recommended; evaluation of peripheral blood via PCR is also useful in establishing a diagnosis of neonatal herpes although it does not assist in identifying the extent of disease. Notably, HSV serologic tests are not a useful diagnostic adjunct. If they are elevated, serum alanine aminotransferase levels may indicate disseminated disease.

Treatment

Strategies to decrease the risk of vertical transmission of HSV include cesarean delivery, maternal prophylactic antiviral therapy, and limiting use of invasive monitoring techniques in mothers shedding HSV at the time of delivery (Brown et al., 2003). Specifically, birth via cesarean delivery for women with active lesions or prodromal symptoms has been shown to reduce the risk of neonatal HSV infection (Pinninti and Kimberlin, 2014b). Maternal

suppressive therapy with acyclovir is known to reduce the frequency of genital lesions near term and the frequency of cesarean delivery, but whether this reduces acquisition of HSV by the neonate remains unclear.

Early treatment with antiviral agents is critical to decrease the risk of serious complications and death. All cases of presumptive neonatal HSV infection should be treated with intravenous acyclovir therapy, with a recommended dosage of 60 mg/kg per day divided every 8 hours (Kimberlin et al., 2001b). A notable side effect of this therapy, however, is transient neutropenia that warrants ongoing monitoring. Nephrotoxicity has also been documented in patients treated with acyclovir, although this appears less common in patients with normal renal function whose fluid status is closely monitored. Treatment is recommended for 14 days for SEM disease and 21 days for disseminated and CNS disease. In cases of CNS involvement, repeated evaluation of CSF for HSV infection via PCR should be performed at the conclusion of therapy, and, if the findings are positive, it should be continued for an additional week.

Acknowledgments

We would like to thank Dakara Rucker Wright and Bernard A. Cohen for their contributions to previous editions of this chapter.

Common Newborn Dermatoses

KATE KHORSAND AND ROBERT SIDBURY

KEY POINTS

- Papulopustular lesions on the palms and/or soles in the first month of life likely represent a self-limited inflammatory process such as eosinophilic pustular folliculitis or infantile acropustulosis, but scabies should be ruled out.
- Neonatal acne (aka *cephalic pustulosis*) is typically multifactorial and self-limited. Treatment is not necessary, but topical agents aimed at reduction of the commensal yeast *Malassezia* can be beneficial.
- Evidence suggests that early use of emollients in infants at risk of developing atopic dermatitis may prevent later disease.
- Subcutaneous fat necrosis of the newborn is generally benign and self-limited but when extensive can cause hypercalcemia.

This chapter describes a group of cutaneous disorders commonly found in neonates. Most of these disorders are benign and are either self-limited or treated with ease. Recognition of these common neonatal dermatoses is important so as to distinguish them from more serious conditions, sparing patients unnecessary work-up and treatment. Each section includes common clinical features and presentation, notes on establishing the diagnosis (with a short differential diagnosis), the cause if known, and a brief discussion of basic treatment and prognosis.

Erythema Toxicum Neonatorum

Clinical Findings

Erythema toxicum neonatorum (ETN) is a benign inflammatory condition affecting newborns. Estimates of incidence range from 7%–41%, and it is seen more commonly in white newborns with a higher birth weight and greater gestational age (Monteagudo et al., 2012). The condition presents in the first 1–3 days after birth as irregularly shaped erythematous macules that can develop overlying vesicles or pustules (Fig. 106.1). ETN most commonly affects the trunk but can involve the face and extremities as well. The palms and soles are typically spared. Affected infants are otherwise healthy. The lesions persist for 1–2 weeks and then spontaneously resolve without sequelae.

Diagnosis

The diagnosis is often clinical but can be further supported by the scraping of a pustule, smearing the contents onto a slide, and

staining with Wright or Giemsa stain (Lucky, 2001). This will reveal a large number of eosinophils. The differential diagnosis of ETN includes other benign entities such as transient neonatal pustular melanosis, miliaria, infantile acropustulosis, and eosinophilic pustular folliculitis. Additionally, infections such as folliculitis, candidiasis, impetigo, and herpes should be considered and ruled out. If a biopsy sample is obtained, histopathologic features include intraepidermal vesicles filled with eosinophils and a mixed intra-dermal inflammatory infiltrate localizing around the superficial pilosebaceous follicle.

Etiology

The cause of ETN remains unclear. Studies have shown the presence of inflammatory mediators, as well as increased eosinophil and macrophage activity (Marchini et al., 2005, 2007) in affected skin compared with unaffected skin. This has led to the theory that ETN could represent a cutaneous immunologic response to microbial colonization of the hair follicles after birth (Marchini et al., 2007).

Treatment and Prognosis

No treatment is required for this benign condition. It is usually asymptomatic. Parents can be reassured and informed that the condition will spontaneously resolve in a matter of weeks. Prolonged courses or recurrence is rare.

Transient Neonatal Pustular Melanosis

Clinical Findings

Transient neonatal pustular melanosis is a benign, self-limited condition that presents at birth in affected infants. It is more common in African-American infants (Badia et al., 2015). There are three clinical phases of transient neonatal pustular melanosis. At birth the neonate has very fragile and superficial 2- to 10-mm pustules located most commonly on the forehead, under the chin, on the low back, and on the shins. These pustules are often wiped off during the initial cleaning after birth. Next, a fine collarette of scale is noted around the resolving pustule. Last, hyperpigmented brown macules develop at the site of the previous pustules (Lucky, 2001; Fig. 106.2). The first two phases usually last 1–2 weeks, but hyperpigmentation can persist for several months (Ghosh, 2015).

Fig. 106.1 Erythema Toxicum Neonatorum. Pinpoint pustules overlying ill-defined erythema on the trunk and extremity of a healthy newborn consistent with erythema toxicum neonatorum.

• **Fig. 106.2** Transient Neonatal Pustular Melanosis. Hyperpigmented macules on the lower back and buttocks, some of which are encircled by scales.

Diagnosis

Diagnosis is clinical, but it can be supported by a scraping from the pustule, with Wright staining of the contents. This will reveal a predominance of neutrophils. The differential diagnosis includes ETN, and these conditions can overlap. Additional considerations include miliaria, acropustulosis of infancy, and infectious diseases such as candidiasis, impetigo, and herpes, which should be ruled out.

Etiology

The underlying cause of transient neonatal pustular melanosis is unknown. Studies linking it with ETN suggest a similar cause.

Treatment and Prognosis

No treatment is required for this benign and self-limited condition. Parents should be informed that while the initial skin findings resolve quickly, the residual hyperpigmentation may take months to completely resolve.

Eosinophilic Pustular Folliculitis

Clinical Findings

Eosinophilic pustular folliculitis (EPF) is a vesiculopustular eruption that can occur in several distinct settings. The infantile form is relatively rare and presents with pruritic follicular lesions typically on the extremities or scalp, although truncal involvement is described. Crops of lesions will occur discretely, not in an annular array as in adults, and persist for days to weeks before resolving without sequelae. EPF tends to present somewhat later than erythema toxicum but has been described on the first day after birth (Buckley et al., 2001).

Diagnosis

Diagnosis is clinical, and persistence past several weeks generally distinguishes EPF from erythema toxicum, although peripheral eosinophilia may be supportive. Histologic examination demonstrates an eosinophilic follicular infiltrate.

Etiology

The cause is unknown.

Treatment and Prognosis

Treatment is symptomatic and can include emollients, topical corticosteroids, and antihistamines. Topical indomethacin therapy has been used in refractory cases (Hashizume et al., 2014).

Acropustulosis of Infancy

Clinical Findings

Acropustulosis of infancy is a relatively uncommon pruritic, vesiculopustular rash that occurs on the hands and feet with spread to the wrists and calves. First described in 1979, this rash is closely related to preceding infections and infestations, with scabies preceding approximately 50% of cases (Paloni et al., 2013; Silverberg, 2015). The eruption is most common in African-American, Hispanic, and Asian children and presents at less than 1 year of age. Crops of intensely pruritic vesicles and pustules appear on the hands and feet, persist for around 2 weeks, and then resolve. Frequent recurrences are the norm, with each eruption decreasing in intensity until eventual complete resolution around 2 to 3 years of age.

Diagnosis

Diagnosis is primarily clinical, and a history of preceding scabies can be quite helpful in making the diagnosis. If a biopsy sample is obtained, it shows necrolysis of the keratinocytes with intraepidermal pustules filled with neutrophils and eosinophils (Vignon-Pennamen and Wallach, 1986). The differential diagnosis includes scabies (concurrent infestation must be ruled out and treated if present), pustular psoriasis, coxsackievirus infection, eosinophilic folliculitis, and less likely, an allergic contact dermatitis.

Etiology

The cause of acropustulosis is unknown, but the condition is known to frequently follow prior scabies infestation or coxsackievirus infection.

• **Fig. 106.3** Numerous grouped milia on the chin of a newborn.

Treatment and Prognosis

The recurrent episodes of acropustulosis of infancy will eventually resolve around 2–3 years of age, but episodes can be managed. Ruling out scabies and treating it if it is present should be a first step (Good et al., 2011). Topical treatment with mid-potency to high-potency corticosteroids is effective for discrete episodes but will not help to prevent relapses (Silverberg, 2015). Historically, acropustulosis of infancy was treated with orally administered dapsone, but this is no longer frequently used because of the risk of hemolysis and methemoglobinemia in patients with glucose 6-phosphate dehydrogenase deficiency.

Milia

Clinical Findings

Milia are an extremely common benign entity, seen at birth in 40%–50% of newborns. They are more common with longer gestations and in infants born to multigravidas (Gupta et al., 2011). Milia (singular, *milium*) are tiny, white monomorphic papules with a smooth surface. They can number from several to dozens. They are an entity distinct from miliaria, which is discussed next. Milia can be present anywhere on the body but occur most commonly on the face, predominantly on the forehead, cheeks, and chin (Fig. 106.3).

Diagnosis

A useful diagnostic tool is expression of the milia contents, which will resemble a tiny white pearl. This is the keratinocyte debris that forms the interior of the cyst. The differential diagnosis includes sebaceous hyperplasia, which would also present on the face but tend to be more yellow, and miliaria, which presents primarily on the body and in greater numbers with distinct clinical variants.

Etiology

Milia are tiny inclusion cysts that form in the epidermis. The epidermal tissue invaginates, often around a vellus hair, and forms a cyst with a wall of keratin-producing cells.

Treatment and Prognosis

Treatment of milia is not required. They tend to resolve spontaneously over several months. Of note, the presence of

multiple large or persistent milia can rarely be associated with syndromes such as epidermolysis bullosa or orofaciocutaneous syndrome.

Miliaria

Clinical Findings

Miliaria is a benign rash due to obstruction of the eccrine duct occurring in the first 1–2 weeks of life, with rapid resolution within days. There are multiple variants depending on the location of the eccrine duct obstruction, with differing clinical presentations. Miliaria crystallina occurs when eccrine ducts within or below the stratum corneum are obstructed and causes small clear vesicles that can be easily wiped away. Miliaria rubra is caused by obstruction of the eccrine duct at the level of the epidermis and is thought to be related to overheating. This causes erythematous papules or papulopustules primarily on the head, neck, face, and trunk. Dermal inflammation contributes to the clinical presentation. Miliaria profunda is caused by occlusion of the eccrine duct at or below the dermal–epidermal junction and causes a mildly inflammatory papular eruption that is rare in newborns.

Diagnosis

The diagnosis of miliaria is made clinically, although scraping of a vesicle or pustule with subsequent Wright staining will reveal few to no cells in miliaria crystallina and lymphocytes in miliaria rubra. The differential diagnosis includes ETN, transient neonatal pustulosis, milia, eosinophilic folliculitis, and infectious entities. Recurrent episodes of pustular miliaria rubra could be a sign of the rare and potentially fatal condition type I pseudohypoaldosteronism, which is an inherited disorder of mineralocorticoid resistance leading to a salt-wasting crisis.

Etiology

Miliaria is caused by obstruction of the eccrine duct, possibly by sweat accumulation. Neonates can have incompletely canalized eccrine ducts, predisposing them to developing obstruction and subsequent miliaria (Dixit et al., 2012).

Treatment and Prognosis

No treatment is required for this benign condition, which will self-resolve. Prevention of overheating can reduce the incidence of miliaria rubra.

Epstein Pearls and Bohn Nodules

Clinical Findings

Epstein pearls and Bohn nodules are very common and benign cysts that form in the mouths of neonates. They present as single or clustered 1- to 2-mm smooth white to yellow papules. Epstein pearls are more often seen in infants born to multigravidas, after longer gestations, and with higher birth weights (Seminario and Ivancakova, 2004). Bohn nodules are often mistaken for natal teeth, prompting referral.

Diagnosis

Epstein pearls are found on the palate, typically at the midline of the junction between the hard and soft palate. Bohn nodules are found on the alveolar ridge, most commonly in the maxillary region. They are distinguishable from neonatal teeth in their location in addition to their appearance; neonatal teeth are usually located in the region of the lower incisors. Radiographic examination would distinguish between these diagnoses (Seminario and Ivanakova, 2004).

Etiology

Both Epstein pearls and Bohn nodules are inclusion cysts. They are thought to originate from remnants of odontogenic epithelium or to potentially be remnants of salivary glands (Dutta et al., 2014).

Treatment and Prognosis

Spontaneous resolution will occur with time, typically within the first several weeks to months after birth. No treatment is required.

Sebaceous Hyperplasia

Clinical Findings

Sebaceous hyperplasia is a common finding, seen in approximately half of newborns (Kanada et al., 2012), and is typically most noticeable surrounding the nose and upper lip. It presents as regular, smooth white to yellow papules that can be grouped around follicles.

Diagnosis

The differential diagnosis includes milia and neonatal acne (neonatal cephalic pustulosis).

Etiology

Sebaceous hyperplasia in newborns is thought to occur secondary to maternal androgens, which stimulate the sebaceous glands in utero (Marchini et al., 2007; Kanada et al., 2012).

Treatment and Prognosis

No treatment is required, and the findings will spontaneously resolve in the first few weeks of life.

Neonatal Cephalic Pustulosis (Neonatal Acne)

Clinical Findings

Neonatal cephalic pustulosis, which is also known by the more common term of *neonatal acne*, consists of erythematous papules and pustules on the cheeks, chin, and forehead of infants (Fig. 106.4). It occurs within the first 30 days after birth and can last up to several months. Comedones are absent. It is an entity distinct from infantile acne, which occurs at 3–6 months of age and can last for years.

• **Fig. 106.4** Neonatal Cephalic Pustulosis (Neonatal Acne). Small monomorphic papules and pustules on the head and neck of a newborn consistent with neonatal cephalic pustulosis or neonatal acne. (From Sidbury R, Paller AS. The diagnosis and management of acne. *Pediatr Ann.* 2000;29:17–24.)

Diagnosis

Diagnosis is made primarily on the clinical appearance, although Wright stain of a smear will reveal neutrophil predominance. The differential diagnosis includes miliaria, milia, ETN, or rarely, severe infectious processes such as candidiasis or folliculitis.

Etiology

The cause of neonatal cephalic pustulosis is debated but is thought to be related to skin colonization with *Malassezia* species. *Malassezia* colonization begins at birth and increases during the first few weeks after birth from approximately 5% of newborns colonized during the first week to 30% colonized by the second to fourth week (Ayhan et al., 2007). This increased *Malassezia* colonization is thought to trigger an inflammatory reaction that some believe becomes neonatal cephalic pustulosis (Bernier et al., 2002; Lucky, 2001). However, others suggest that the degree of skin colonization by *Malassezia* does not differ between affected and unaffected infants and that there is no correlation between the severity of disease and *Malassezia* isolation (Ayhan et al., 2007). If, and why, *Malassezia* colonization causes an inflammatory reaction in some neonates but not in others is undetermined.

Treatment and Prognosis

No treatment is required for this benign self-limited condition. However, the lesions can take months to resolve. Topical treatment with imidazole antifungals, such as clotrimazole, econazole, or ketoconazole, may be effective at shortening the duration of the eruption.

Seborrheic Dermatitis

Clinical Findings

In newborns, seborrheic dermatitis (SD) is an extremely common finding and presents as irregular salmon pink patches with waxy scaling on the scalp, forehead, and nasolabial folds. It can also involve the diaper area. Appearing around 2–4 weeks of age, this condition usually resolves or abates by 1 year of age. Severe cases can become secondarily infected. A strong association between atopic dermatitis (AD) and infantile SD has been postulated, suggesting that infantile SD may precede the development of AD or that these conditions may be on the same spectrum of disease (Alexopoulos et al., 2014).

Diagnosis

Diagnosis is clinical, and the differential diagnosis includes AD, psoriasis, Langerhans cell histiocytosis, or another superficial fungal infection. AD may overlap with SD, as discussed previously, and psoriasis does not typically present this early. Langerhans cell histiocytosis is a more serious, but fortunately rare, condition.

Etiology

In adults, SD is related to *Malassezia* overgrowth, but it is unclear if this is the pathogenesis behind the disorder in infants, although that has been suggested by several historical studies (Broberg and Faergemann, 1989; Ruiz-Maldonado et al., 1989).

Treatment and Prognosis

This condition often resolves spontaneously or abates by 1 year of age. Both topical antifungals and topical steroids have been used to treat this condition. Ketoconazole was shown to be equally as efficacious at treating SD as steroid creams such as hydrocortisone (Cohen, 2004), and therefore this could be a viable treatment option. Treatment of the scalp with olive oil should be avoided, as this medium can encourage yeast growth (Siegfried and Glenn, 2012).

Atopic Dermatitis

Clinical Findings

AD is an extensive topic, spanning all ages of childhood into adulthood. This section will focus on infantile AD, as there are multiple informational sources for this common and important condition as it pertains to later childhood. AD, commonly known as *eczema*, is a chronic, relapsing condition defined by distinctive cutaneous manifestations and associations with additional atopic conditions such as asthma and allergic rhinitis. It is extremely common, affecting 15%–20% of the population, particularly in developed countries. In more than half of cases, the onset of AD is in infancy (Kay et al., 1994). In infants the most common areas of involvement include the cheeks (often seen concurrently with an irritant dermatitis secondary to saliva), neck, flexural folds, wrists, and ankles. In infantile eczema, involvement of the extensor surfaces (skin on the opposite side of a joint) and trunk is seen more commonly than flexural involvement. Erythema, scaling, lichenification, and excoriation are common clinical findings. Itch is the predominant symptom. The diaper area and nasal tip are

notably spared. Superinfection can be common. There is significant overlap with SD, as discussed previously. As infants age, the “typical” presentation of AD often evolves with prominent involvement of the antecubital and popliteal fossae with associated diffusely dry skin.

Diagnosis

Diagnosis is made clinically, and biopsy is rarely performed. The differential diagnosis of AD is broad and includes common entities such as SD, contact dermatitis, and irritant dermatitis. More rarely, severe AD can be associated with recurrent infections of various forms in multiple rare immunologic disorders, including Wiskott–Aldrich syndrome, chronic granulomatous disease, hyper-immunoglobulin E (IgE) syndrome, and severe combined immunodeficiency. Severe recalcitrant eczema with other unusual infections should raise awareness of these serious conditions particularly in the setting of failure to thrive. If lesions appear superinfected with crusting, bacterial culture should be performed.

Etiology

The exact cause of AD remains elusive. At its core, AD appears to be a condition of defective skin barrier function and immune alteration. In AD, there is a prominence of the T-helper2–T-cell subsets, which produce interleukin-4 and promote production of IgE, eosinophilia, mast cell proliferation, and release of histamine. Loss of filaggrin mutations has been linked to individuals with early-onset and persistent AD (Palmer et al., 2006; Brown et al., 2008). Filaggrin acts in the top layer of the skin and maintains skin barrier function. When the skin’s barrier function is impaired, it is increasingly susceptible to exogenous triggers. Nearly all patients with AD carry *Staphylococcus aureus* on their skin, and staphylococcal exotoxins can act as superantigens that stimulate T-cell responses (Leung, 1995). The impact of food and food allergy, a common question from parents, is only relevant in a minority of patients. Food allergies are more common in atopic individuals, and in some cases of AD recalcitrant to treatment, food allergies may play a role in the persistence of the disease. A Cochrane review stated that maternal dietary antigen avoidance during pregnancy had no impact on the development of AD in the first 18 months of life and could increase the risk of preterm birth or decreased birth weight (Kramer and Kakuma, 2014). Breastfeeding during the first 4 months of life has been shown to reduce the incidence and severity of AD in high-risk infants (Blattner and Murase, 2014), although prolonged breastfeeding has not impacted its incidence (Flohr et al., 2011).

Treatment and Prognosis

There is no cure for eczema; therefore the goal of treatment is to manage signs and symptoms and reduce recurrences. Spontaneous resolution often occurs as children age. Maintenance therapies include gentle bathing techniques such as limiting a gentle soap to soiled areas and avoidance of long, hot bathing. Diligent moisturization at least twice daily and always after bathing with a thick, bland emollient is important to restore cutaneous moisturization and maintain barrier function. Treatment of active rash with appropriate strength topical corticosteroids, rarely stronger than class 6 or 7 (e.g., hydrocortisone 2.5% or 1%, respectively) is first-line treatment for symptomatic AD refractory to emollients

• **Fig. 106.5** Diaper dermatitis.

and good skin care. Second-line agents include topical calcineurin inhibitors such as tacrolimus or pimecrolimus, but these agents are not approved for use in children younger than 2 years. Adjunctive topical or systemic antibiotics address concurrent skin infection when present, and dilute bleach baths may be preventive (Huang et al., 2009). Treating inflammation as described earlier is the best way to reduce itch, but when there is sleep disruption, a sedating antihistamine such as diphenhydramine or hydroxyzine may help, if it is age appropriate.

Diaper Dermatitis

Clinical Findings

Diaper dermatitis (DD) is likely the most common skin condition of infants. The vast majority of affected infants are otherwise healthy, but occasionally DD can suggest an underlying systemic disorder. DD is primarily an irritant process, occurring when the skin in contact with the diaper becomes inflamed because of friction and contact with urine, feces, cleansing materials, and other irritants. The clinical presentation includes erythema, with mild scaling of the gluteal crease, buttocks, and convex surfaces of the pubic area and perianal rim (Fig. 106.5). There is often relative sparing of the skinfolds, which are protected from direct contact with the diaper. Erosions or plaques can be present in more severe cases, and discrete ulcerations are seen in a severe form of DD known as *Jacquet dermatitis*. This distinctive noduloerosive presentation is seen more frequently in association with cloth diaper use.

Diagnosis

DD is a clinical diagnosis, and as such, histopathology is usually not helpful. Other infectious and noninfectious causes of rashes in the diaper area should be excluded. Infectious causes of diaper rashes include congenital syphilis and infections caused by *Candida* or other fungi, *Streptococcus*, *Staphylococcus* (including staphylococcal scalded skin syndrome), herpes simplex virus, and human immunodeficiency virus. These infectious diaper area eruptions are usually clinically distinct. *Candida* infections present with bright red, relatively well-demarcated patches and plaques with satellite lesions in the groin region and perianal rim. Staphylococcal infection presents most commonly in the diaper area as bullous

impetigo with scattered bullae and vesicles. Streptococcal infections present as a brightly erythematous perianal patch. Skin findings caused by infections are often found in areas additional to the diaper region. Other considerations include infantile SD, allergic contact dermatitis, nutritional deficiencies (such as acrodermatitis enteropathica in zinc deficiency), Langerhans cell histiocytosis, and rare metabolic disorders. Similar findings will often be identified in other nondiapered skin areas, which can be a distinguishing feature.

Etiology

DD is exceedingly common, with most infants experiencing one or more episodes. Multiple factors contribute, including occlusion friction, and maceration. When the barrier has been compromised by these factors, chemical or biologic irritants in urine and feces continue to drive the dermatitis. Further irritants such as soaps, diaper wipes, and numerous topical products perpetuate the problem.

Treatment and Prognosis

Prevention of DD starts with maintenance of skin barrier function and prevention of irritation. The use of disposable diapers, particularly the superabsorbent variety, has been shown to be better at preventing DD than the use of cloth diapers (Lane et al., 1990). Avoiding prolonged skin contact with soiled diapers is an important aspect of basic infant care. Potential irritants or sensitizers should be identified and removed. Commercial diaper wipes are a common culprit. Barrier pastes such as zinc oxide ointment and zinc paste as well as petroleum jelly are bland skin protectants. Thick layers of these protective agents should be applied, and with diaper changes, only a partial layer should be removed to protect the underlying skin. Mineral oil provides a way to remove zinc preparations without rubbing the skin excessively. In the absence of *Candida* infection, a low-potency topical steroid can be helpful. If *Candida* infection is suspected, an anti-*Candida* agent can be added. Daily bathing is acceptable, but harsh soaps and scrubbing should be avoided. DD is self-limited and episodic.

Harlequin Color Change

Clinical Findings

Harlequin color change is a rare but benign event. It was first reported in 1952. It represents an abrupt deep vascular red color change to one side of the body, with contralateral blanching and sharp midline demarcation. It can involve the entire body or can be more localized to a single body area. It occurs most commonly in the newborn and is more often seen in premature infants.

Diagnosis

Diagnosis is by clinical appearance. Rapid resolution is the norm.

Etiology

Harlequin color change is thought to be due to the immaturity of the hypothalamic control center in newborns, which causes asymmetric control of the sympathetic peripheral vascular tone, resulting in skin color change with a sharp midline demarcation.

• **Fig. 106.6** Subcutaneous Fat Necrosis. Brawny, indurated, erythematous plaque on the back of an otherwise healthy infant with associated hypercalcemia.

Treatment and Prognosis

No treatment is required for this entity. It is benign and rapidly resolves on its own. Recognition and education are important as harlequin color change is a surprising and alarming occurrence for parents. Harlequin color change is unrelated to harlequin ichthyosis.

Subcutaneous Fat Necrosis

Clinical Findings

Subcutaneous fat necrosis is a relatively uncommon condition affecting full-term infants within the first several weeks after birth. It presents as single or multiple, poorly demarcated, tender nodules and plaques that are firm and have an underlying dusky reddish-purple hue (Fig. 106.6). The lesions are located in areas with fat pads, including the buttocks, thighs, arms, face, and shoulders. Calcification of the lesions can occur and can be associated with hypercalcemia.

Diagnosis

Skin biopsy will reveal subcutaneous granulomatous infiltration with multinucleated giant cells and damaged lipocytes containing characteristic needle-shaped clefts. Soft tissue necrosis and inflammation may cause local production of vitamin D, leading to hypercalcemia. Differential diagnosis includes sclerema neonatorum, which is a rare life-threatening panniculitis characterized by diffuse, progressive skin hardening.

Etiology

Subcutaneous fat necrosis is thought to be caused by some form of intrauterine or perinatal trauma. It has been associated with maternal cocaine use, hypothermia, meconium aspiration, and perinatal asphyxia (Rubin et al., 2015).

Treatment and Prognosis

This condition is often self-limited, but care must be taken to monitor calcium levels because of the risk of severe hypercalcemia

and to assess the newborn for evidence of renal injury because of nephrocalcinosis (Tuddenham et al., 2015). Appropriate immediate treatment should be instituted if there is evidence of either of these complications. Resolution of subcutaneous fat necrosis occurs over a period of weeks to months. Bisphosphonates have been suggested for use in subcutaneous fat necrosis, but appropriate controlled clinical trials are still lacking.

Cutis Marmorata

Clinical Findings

Cutis marmorata is a common finding, particularly in premature infants. It presents with a netlike violaceous reticular blanching pattern affecting the extremities more than the trunk. It is exaggerated with cooling and resolves with warming.

Diagnosis

Diagnosis is made by clinical observation. Findings should resolve with warming, and the condition itself should resolve by approximately 1 month of age. Persistent cutis marmorata past 1 month of age can be associated with genetic abnormalities such as Down syndrome, trisomy 18, and Cornelia de Lange syndrome. Cutis marmorata that persists after warming and is localized and asymmetric could represent cutis marmorata telangiectatica congenita, a distinctive vascular anomaly that can be associated with limb atrophy. Another diagnostic possibility is livedo reticularis, which presents with a clear vascular pattern that can be related to underlying vascular inflammation/vasculitis; however, this condition is quite rare in infants.

Etiology

Cutis marmorata occurs because of transient shifts in skin blood flow.

Treatment and Prognosis

Warming should resolve the cutaneous findings. If cutis marmorata is unresponsive to warming or persists past several months of age, further work-up for underlying causes may be required.

Dermal Melanocytosis

Clinical Findings

Dermal melanocytosis (DM), previously known as *Mongolian spots*, is an exceedingly common congenital cutaneous finding in children of African-American, Asian, and Hispanic descent. It presents as well-demarcated, deep blue to gray pigmented macules and patches that are most commonly seen on the buttocks and low back (Fig. 106.7). DM is usually an isolated finding and is not typically associated with tissue malformations or systemic disorders. There are very rare case reports of DM associated with inborn errors of metabolism (e.g., GM1 gangliosidosis) and other potential associations with a vascular nevus called *phakomatosis pigmentovascularis*, which is a form of twin spotting that occurs when two genetically distinct patches involve nearby or corresponding body areas (Franceschini and Dinulos, 2015).

• **Fig. 106.7** Dermal Melanocytosis. Gunmetal gray macules and patches on the back of a healthy infant consistent with dermal melanocytosis (aka *Mongolian spots*).

Diagnosis

Diagnosis is by clinical appearance. The differential diagnosis includes postinflammatory hyperpigmentation, nevus of Ito, vascular malformation, and child abuse. Bruising concerning for child abuse is suggested when the color of the lesion changes over time from blue green to brown and if the lesion is tender to palpation. Biopsy of DM is rarely performed but would show increased numbers of dermal melanocytes.

Etiology

DM is caused by an excessive number of dermal melanocytes. The bluish-gray coloration is due to the Tyndall effect (light reflection off the dermal-based melanocytes).

Treatment and Prognosis

No treatment is required for this benign and self-limited condition. DM tends to fade over time, with studies showing that 42% of cases disappear by 1 year of age (Gupta and Tappa, 2013). Features that portend persistence past 1 year of age are multiple dark and/or large patches and presence in locations other than the sacrum. Most of these lesions fade by several years of age. Laser treatment of the lesions is not recommended. Because of possible confusion with bruising as mentioned earlier, it may be prudent to document DM when it is first encountered.

Aplasia Cutis Congenita

Clinical Findings

Aplasia cutis congenita (ACC) is a rare congenital skin defect that is localized and is most often seen on the scalp as an isolated lesion (Tollefson, 2012). It presents with a localized loss of skin of variable

thickness and is rarely associated with underlying skeletal abnormalities. Findings can include an open ulceration or a healed atrophic scar. The clinical finding of a “hair collar sign” that presents as a ring of darker, longer hair surrounding the lesion represents an increased risk of an underlying neurodevelopmental abnormality.

Diagnosis

Diagnosis is clinical. Imaging of the central nervous system should be performed if a hair collar sign is present. Variants of ACC include focal dermal hypoplasia, or Goltz syndrome. Scalp ulcerations can be seen in infectious processes such as herpes simplex virus infection or can be due to perinatal trauma such as scalp electrode placement. Extensive ACC may be associated with limb hypoplasia (e.g., Adams–Oliver syndrome) or a variant of epidermolysis bullosa (e.g., congenital localized absence of skin, aka *Bart syndrome*).

Etiology

There are numerous theories regarding the cause of ACC. These include primarily intrauterine events such as intrauterine trauma, vascular abnormalities, intrauterine infection, and maternal medications (Browning, 2013). No firm cause has been elucidated to date.

Treatment and Prognosis

The lesions of ACC will heal without intervention but scarring will be present. Identification and management of the rare underlying neurodevelopmental abnormality are important aspects of care for these patients. In especially large lesions, surgical intervention may be required to close the defect. Scar revision can be performed later in life if desired.

Cutaneous Congenital Defects

DEEPTI GUPTA AND ROBERT SIDBURY

KEY POINTS

- Infantile hemangiomas (IHs) are the most common soft tissue tumor of infancy, with a reported incidence of 4%–5% in mature newborns and up to 23% in extremely preterm infants.
- There is often parental concern regarding the risk of hemorrhage in IHs, but serious bleeding rarely occurs, and there is not a risk of coagulopathy or Kasabach–Merritt phenomenon.
- Propranolol is a nonselective beta blocker that was serendipitously discovered to effectively treat IHs.
- Port-wine stains can occur in isolation but also can be related to an underlying genetic disorder, of which *Sturge–Weber syndrome* is the most common. Laser therapy can yield remarkable improvement for many port-wine stains, minimizing the emotional pain that accompanies facial disfigurement.
- Localized areas of hypopigmentation on the skin of the newborn may be isolated phenomena or they may be markers of extracutaneous abnormalities.
- Congenital melanocytic nevi are hamartomas derived from neural crest cells that form in utero and are often classified by the largest diameter of their adult projected size. The risk of melanoma in small and intermediate-sized nevi is low, but for large and giant congenital melanocytic nevi, the risk of melanoma is higher, ranging from 4.5%–10%.

The spectrum of congenital cutaneous defects can be organized by the type of tissue or cell of origin or on the basis of the location within the skin. This chapter presents information on the most common and clinically significant congenital cutaneous defects.

Vascular Anomalies

There has been long-standing confusion regarding the nomenclature and pathogenesis surrounding cutaneous vascular anomalies, which has led to delays in diagnosis and improper treatment and management. Terms such as *cavernous hemangioma* were used to describe both vascular tumors and vascular malformations, and terms such as *hemangioma* have been used indiscriminately to encompass various vascular tumors of differing behavior, prognosis, morphology, and treatment. A classification system for vascular anomalies was originally proposed by Mulliken and Glowacki (1982) and was most recently updated in 2015 (Wassef et al., 2015) by the

International Society for the Study of Vascular Anomalies to allow more precise diagnosis, categorization, and management. Vascular anomalies can be largely divided into two groups—vascular tumors and vascular malformations, with a smaller third group of provisionally unclassified vascular anomalies (Table 107.1). Vascular tumors demonstrate cellular hyperplasia, while vascular malformations comprise a single malformed and dysplastic vessel or a combination of such vessels (Enjolras and Mulliken, 1997, and Finn et al., 1983). Vascular tumors can be further subdivided into benign, locally aggressive, and malignant tumors. Vascular malformations are subdivided into categories based on the predominant type of anomalous channel, arising either from a single abnormal channel type or a mixed malformation comprising a combination of capillary, venous, lymphatic, or arterial vessel involvement. Simple and combined vascular malformations can be further divided according to their flow characteristics. Vascular malformations can also be classified by their association with other clinical features or associated syndromes (Table 107.2). A complete list of the various vascular tumors and malformations is given in Table 107.1, with highlighting of the most common vascular anomalies described within the text.

Vascular Tumors

Infantile Hemangiomas

Infantile hemangiomas (IHs) are the most common soft tissue tumor of infancy. They have a reported incidence of 4%–5% (Haggstrom et al., 2007; Kilcline and Frieden, 2008; Munden et al., 2014) in mature newborns, and incidence rates of up to 23% have been reported in preterm infants weighing less than 1000 g (Goelz and Poets, 2015). Infantile hemangiomas have a female (2.3 to 2.9 times higher) and white predominance (Esterly, 1995). The most significant risk factor for the development of IHs is low birth weight, with the risk increasing by 40% for every 500-g decrease in birth weight (Drolet et al., 2008). Additional risk factors include prematurity, multiple gestation, preeclampsia, placental abnormalities, advanced maternal age, and in vitro fertilization (Kilcline and Frieden, 2008; Munden et al., 2014).

Clinical Features

IHs have a characteristic and unique growth pattern that is similar in both full-term and premature infants. At birth, IHs are either absent or barely evident. Within the first few weeks after birth, a precursor lesion is present, which can appear as either a pale area of vasoconstriction or a telangiectatic red macule or a “bruise-like”

• **Fig. 107.1** A hemangioma precursor sign presenting as a pale vasoconstrictive halo surrounding two faint erythematous macules on the lumbosacral region of an infant.

area (Fig. 107.1). There is a short latency period of 1 to 3 weeks before initiation of a rapid proliferation phase in most hemangiomas. This rapid growth phase occurs within the first 3 months after birth, with most of the growth occurring between 5 and 8 weeks of age (Tollefson and Frieden, 2012). It is important to note that

up to 80% of IHs have completed their growth by 3 months of age. Their growth is also limited to increasing volume within a predefined area rather than exhibiting a true radial growth phase, which is seen more characteristically in other neoplasms (Chang et al., 2008). After a more rapid growth phase, IHs can continue to grow more slowly up until 9 to 12 months of age. There is then an observed phase of relative stabilization followed by spontaneous regression. Regression of a hemangioma occurs slowly over many years, with approximately 90% regression noted by 4 years of age (Bauland et al., 2011). Clinical signs of regression include dulling of the bright red color to a more purple color and a central gray-white discoloration that spreads centrifugally. If the white discoloration occurs in infants younger than 3 months, it can sometimes be a marker of impending ulceration. Regression does not indicate complete resolution and normalization of the underlying skin in all cases. There can be remaining telangiectasias, distortion of facial anatomy, and permanent textural changes characterized by residual fibrofatty tissue and skin laxity because of loss of elastic fibers causing fine wrinkling of tissue. Permanent scarring can also result from hemangiomas that were previously ulcerated.

While proliferation is often a key characteristic of IHs, it should not be considered an absolute defining feature. There is a unique subset of IHs known as *abortive hemangiomas* or *infantile hemangiomas with minimal or absent growth* in which the proliferation phase is absent (Suh and Frieden, 2010; Fig. 107.2). These hemangiomas present preferentially on the lower extremities and sometimes can be confused with capillary malformations (CMs). Although they lack the proliferation phase, they do spontaneously regress.

TABLE 107.2 Syndromes Associated With Vascular Malformations

| Vascular Malformation Type | Associated Syndrome | Clinical Features | Other Features |
|--|--|--|--|
| Capillary malformation/ port-wine stain | Sturge–Weber syndrome | <ul style="list-style-type: none"> - Facial port-wine stain (often involving forehead or V1 distribution) - Ipsilateral eye abnormalities (choroidal vascular anomalies, increased ocular pressure, buphthalmos, glaucoma) - Leptomeningeal and brain abnormalities | Mutations in <i>GNAQ</i> in syndromic and nonsyndromic port-wine stains identified |
| | Nova syndrome | <ul style="list-style-type: none"> - Capillary malformation of the glabella - Neurologic malformations (Dandy–Walker malformation, hydrocephalus, cerebellar agenesis, mega cisterna magna) | |
| | Phakomatosis pigmentovascularis | <p>Combination of cutaneous vascular and pigmentary abnormalities</p> <p>Classification into five subtypes:</p> <ol style="list-style-type: none"> 1. Capillary malformation, epidermal nevus 2. Capillary malformation, dermal melanosis, with or without nevus anemicus 3. Capillary malformation, nevus spilus, with or without nevus anemicus 4. Capillary malformation, dermal melanosis, nevus spilus, with or without nevus anemicus 5. Cutis marmorata telangiectasia congenita, dermal melanosis | Phakomatosis pigmentovascularis has been associated with other vascular anomaly syndromes, including Sturge–Weber syndrome and Klippel–Trenaunay syndrome |
| | Beckwith–Wiedemann syndrome | <ul style="list-style-type: none"> - Prominent nevus simplex/capillary malformation of the philtrum and glabella - Hemihypertrophy - Visceromegaly - Macroglossia - Omphalocele | Intelligence is often not impaired. Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended |
| | Macrocephaly–capillary malformation syndrome/ megalencephaly–capillary malformation– polymicrogyria syndrome | <ul style="list-style-type: none"> - Macrocephaly - Capillary malformation most prominent of the central face (philtrum and glabella) but can occur anywhere - Overgrowth of the body and brain (megalencephaly, hemihypertrophy) - Brain malformations (polymicrogyria, hydrocephalus) - Digital abnormalities (syndactyly, polydactyly) - Joint laxity | Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended. <i>AKT3</i> , <i>PIK3CA</i> , <i>PIK3R2</i> mutations detected. Developmental delay and seizures often occur. |
| Venous malformations | Blue rubber bleb nevus syndrome (Bean syndrome) | Multifocal venous malformations of the skin, mucosa, and gastrointestinal tract. Present as small black-blue papules and skin-colored nodules. Involvement of the palms and soles is common. Gastrointestinal bleeding is common. | Gastrointestinal bleeding is common and is a unique feature of Blue rubber bleb nevus syndrome. Bleeding can result in chronic anemia and can require transfusions |
| | Glomuvenous malformation syndrome | Small to large segmental venous malformations with cobblestoned appearance and bluish-purple color. Often painful to palpation | Autosomal dominant inheritance or sporadic, mutations in glomulin gene (<i>GLMN</i>) |
| | Familial venous malformation cutaneous and mucosal | Small venous malformations mainly involving skin and mucosa but can also involve gastrointestinal tract, brain, and skeletal muscle. Usually asymptomatic | Autosomal dominant inheritance. Often associated with <i>Tie2</i> mutation. |
| | Maffucci syndrome | <ul style="list-style-type: none"> - Venous malformation like skin nodules, rare presentation in infancy - Enchondromas, benign cartilage-forming tumors within the medullary cavity of the bone leading to bony distortion, fragility, and shortening of the affected limb. Hands and feet are involved 90% of the time. | Malignant transformation of the enchondromas can occur over time. Somatic mosaic mutations in <i>IDH1</i> and <i>IDH2</i> have been identified in cases |
| | Cutis marmorata telangiectatica congenita | <ul style="list-style-type: none"> - Capillary malformation, reticulated, can have focal areas of atrophy and ulceration (see Fig. 107.34) - Limb asymmetry of affected limb. | Other reported abnormalities: glaucoma and other ocular anomalies, cardiac defects, syndactyly, brain and spinal cord abnormalities |

| Arteriovenous malformation | Capillary malformation–arteriovenous malformation syndrome | <ul style="list-style-type: none"> - Multiple capillary malformations, congenital and acquired - Arteriovenous malformations of the central nervous system and soft tissues | Autosomal dominant Mutation in <i>RASA1</i> |
| | Cobb syndrome | <ul style="list-style-type: none"> - Spinal arteriovenous malformation - Vascular malformation of the skin (extremities or trunk) | |
| | Hereditary hemorrhagic telangiectasia | <ul style="list-style-type: none"> - Telangiectasias of the skin and mucosa - Epistaxis - Arteriovenous malformation of the lungs, brain, and liver | Autosomal dominant Infants with hereditary hemorrhagic telangiectasia can present with intracranial hemorrhage in the neonatal period |
| Vascular malformation and overgrowth syndromes | Beckwith–Wiedemann syndrome | <ul style="list-style-type: none"> - Prominent nevus simplex/capillary malformation of the philtrum and glabella - Hemihypertrophy - Visceromegaly - Macroglossia - Omphalocele | Intelligence is often not impaired. Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended |
| | Macrocephaly–capillary malformation syndrome/megalencephaly–capillary malformation–polymicrogyria syndrome | <ul style="list-style-type: none"> - Macrocephaly - Capillary malformation most prominent of the central face (philtrum and glabella) but can occur anywhere - Overgrowth of the body and brain (megalencephaly, hemihypertrophy) - Brain malformations (polymicrogyria, hydrocephalus) - Digital abnormalities (syndactyly, polydactyly) - Joint laxity | Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended. <i>AKT3</i> , <i>PIK3CA</i> , and <i>PIK3R2</i> mutations detected. Developmental delay and seizures often occur. |
| | Klippel–Trenaunay syndrome | <ul style="list-style-type: none"> - Combined slow-flow vascular malformation (capillary malformation, capillary malformation–venous malformation, capillary malformation–lymphatic malformation–venous malformation) in a characteristic geographic morphology - Venous varicosities - Overgrowth or undergrowth of the affected limb - Leg length discrepancy | At risk of coagulopathy, pulmonary embolism, contractures |
| | Parkes Weber syndrome | <ul style="list-style-type: none"> - Fast-flow vascular malformation (arteriovenous malformation) and arteriovenous shunts - Vascular stain - Overgrowth of the affected limb - Leg length discrepancy | Can occur as part of capillary malformation–arteriovenous malformation syndrome due to <i>RASA1</i> mutation, therefore family history should be obtained |
| | CLOVES syndrome | <ul style="list-style-type: none"> - Combined vascular malformation (capillary malformation, capillary malformation–lymphatic malformation–venous malformation, lymphatic malformation, arteriovenous malformation) - Epidermal nevus - Lipomas/truncal lipomatosis - Skeletal anomalies/scoliosis - Sandal gap deformity of toes | <i>PIK3CA</i> mutation. Risk of Wilms tumor |
| | Proteus syndrome | <ul style="list-style-type: none"> - Slow-flow vascular malformation (capillary malformation, capillary malformation–lymphatic malformation–venous malformation, lymphatic malformation) - Connective tissue nevi | Growth is progressive. |
| | <i>PTEN</i> hamartoma tumor syndrome (Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome) | <ul style="list-style-type: none"> - Vascular malformation (arteriovenous malformation, lymphatic malformation) - Epidermal nevus - Collagenomas - Lipomatosis | Segmental overgrowth. At risk of internal malignancies such as breast, thyroid, and endometrial cancers. Syndrome has characteristics of penile lentiginos, developmental delay, and macrocephaly |

• **Fig. 107.2** Infantile hemangioma with minimal or absent growth. A 4-month-old male with a reticulated vascular patch on the lower back.

• **Fig. 107.3** Infantile hemangioma, superficial type, located on the upper arm of an infant.

• **Fig. 107.4** Infantile hemangioma, deep type, located on the lower back of an infant.

• **Fig. 107.5** Infantile hemangioma, mixed type, with both superficial and deep components.

The clinical appearance of an infantile hemangioma is dictated by the depth of involvement, which can also lend itself to differences in the timing of growth. Superficial hemangiomas (Fig. 107.3) are located in the upper dermis and present as elevated bright-red, well-demarcated, papules or plaques, which are sometimes in lay language referred to as *strawberry hemangiomas*. In their early proliferation phase, small bright-red papules can be seen arising from fine telangiectatic vessels, which can be a distinguishing feature between IHs and CMs that can have a similar appearance in early infancy. Deep infantile hemangiomas (Fig. 107.4) are confined to the deep dermis and subcutis and present as bluish, dome-shaped tumors or nodules, with ill-defined borders. They can present in isolation or more commonly as a mixed infantile hemangioma (Fig. 107.5) with both superficial and deep components. The deep component of IHs often has a distinct growth pattern in which they tend to appear later, around 2 to 3 months of age, and grow for a longer period, sometimes even over years, as compared with their superficial counterparts (Brandling-Bennett et al., 2008; Chang et al., 2008). Hemangiomas are further characterized by their shape, pattern, and extent of involvement—whether focal or segmental. Focal hemangiomas seem to grow from a single point, whereas

segmental hemangiomas are thought to arise from an embryonic developmental unit or placode and comprise a pattern on the skin correlating with these developmental units. Segmental hemangiomas are at risk of associated anomalies and syndromes. Large facial or scalp hemangiomas should be evaluated for the possibility of PHACE (posterior fossa abnormalities, infantile hemangioma, arterial abnormalities, coarctation of the aorta, eye abnormalities) syndrome, which can also have associated midline defects such as supraumbilical raphe and sternal cleft abnormalities and therefore are sometimes referred to as PHACES. Perineal hemangiomas or segmental hemangiomas in the lumbosacral area should be evaluated for the possibility of underlying spinal and genitourinary abnormalities with possible LUMBAR (lower body hemangioma, urogenital abnormalities, ulceration, myelopathy, bony deformities, anorectal malformations, and renal abnormalities) syndrome, also known as SACRAL (spinal dysraphism, anogenital abnormalities, cutaneous, renal and urologic abnormalities, associated with angioma of the lumbosacral localization) or PELVIS (perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag) syndrome. Segmental hemangiomas, like deep IHs, can sometimes have a prolonged growth phase, which in rare cases may last for years.

There is often parental concern regarding the risk of hemorrhage in IHs, and parents should be reassured that serious bleeding rarely occurs. Coagulopathy and risk of Kasabach–Merritt phenomenon (KMP) was originally thought to be associated with large infantile hemangioma, but it has been shown that KMP does not occur with IHs and is seen only with other vascular tumors, such as tufted angiomas and kaposiform hemangioendotheliomas (Enjolras et al., 1997).

Pathogenesis

IHs form as a result of dysregulation of both vasculogenesis and angiogenesis. There are many proposed theories as to the trigger that initiates this dysregulation, without any one unifying cause, but it is likely that hypoxia plays an important role. There is strong evidence in support of IHs being derived from endothelial stem and progenitor cells (Khan et al., 2008). Isolation of CD133⁺ endothelial progenitor cells from infantile hemangioma tissue and injection of these progenitor cells into nude mice lead to formation of tumors with the unique immunohistochemical and growth characteristics of IHs (Khan et al., 2008). The endothelial cells that were isolated from IHs were also found to be clonal in nature, suggesting that these tumors were caused by a somatic mutation in one or more genes regulating endothelial cell proliferation (Boye et al., 2001). The endothelial cells in infantile hemangioma express a unique phenotype of cell surface markers with positive staining for glucose transporter 1 (GLUT1), merosin, and antigen Lewis Y, which is also expressed by placental endothelial cells, but are not present in any other tumor or vascular malformation (North et al., 2001). Histologically, IHs have increased cellularity and form small sinusoidal vascular channels. It has been suggested that IHs may result from ectopic placental tissue given the similarity in their endothelial cell profiles and the fact that the placenta and IHs share a similar life cycle (North et al., 2000). Further evidence suggestive of this link relates to the increased risk of development of IHs in low birth weight infants—particularly those whose mothers had preeclampsia or placenta previa, both of which are associated with placental hypoxia. Hypoxia likely plays a large role in the development of IHs and is thought to be an important triggering signal for their development (Drolet and Frieden, 2010; Léauté-Labrèze et al., 2017), with in utero hypoxia as a risk factor for localized hemangiomas and regional hypoxia from arterial abnormalities as a risk factor for segmental hemangiomas. It is likely that this hypoxic stress acts as a triggering signal and leads to overexpression of vascular endothelial growth factor via the hypoxia-inducible factor α pathway, which then leads to proliferation of CD133⁺ endothelial progenitor cells that are present in fetal tissue and causes them to differentiate into immature endothelial cells, along with pericytes, dendritic cells, and mesenchymal cells with adipogenic potential. The adipogenic potential may play a role during regression—when blood vessels are replaced with fibrofatty tissue. During the involution phase, endothelial cells are also noted to express caspases, which are known markers of apoptosis.

Diagnosis

In most cases a hemangioma can be diagnosed by its clinical appearance and characteristic pattern of evolution. A lesion that deviates from this typical picture presents a diagnostic dilemma. Doppler ultrasound examination can be easily performed and may be helpful in distinguishing between an infantile hemangioma and another low-flow malformation or nonvascular tumor. Other imaging modalities—magnetic resonance imaging (MRI) or angiography—may be indicated for large or obstructive lesions

(e.g., ocular, upper airway) to help define the extent of involvement or associated abnormalities (e.g., PHACE or LUMBAR syndrome) (Baker et al., 1993; Esterly, 1995). Skin biopsy is diagnostic for nonvascular tumors, which can mimic vascular birthmarks (e.g., pilomatricoma, juvenile xanthogranuloma [JXG], Langerhans cell histiocytosis, infantile myofibromatosis, rhabdomyosarcoma). IHs can also be differentiated from other vascular tumors by staining with GLUT1, an immunohistochemical marker that is highly selective and specific for IHs. GLUT1 is also expressed at the blood–brain barrier and in placental tissue but has not been found in any other vascular tumors, including congenital hemangiomas. Its discovery has helped in making the correct diagnosis of these vascular tumors, especially in cases with atypical presentations (North et al., 2000).

Complications

While the majority of IHs are uncomplicated and spontaneously regress without any need for intervention, in approximately 10%–15% of cases, complications can arise requiring treatment.

Local Complications

Ulceration. Ulceration is the most common complication observed in IHs and can be seen in up to 30% of cases (Maguiness and Frieden, 2012; Fig. 107.6). It can cause significant pain and discomfort and permanent scarring in the area of ulceration. Ulceration has been described to be more likely to occur during two points during the life cycle of the hemangioma: either just before the rapid proliferation phase, which can be the presenting sign of the hemangioma, or at the end of the growth phase (usually around 4 months of age). The exact mechanism causing ulceration is unknown but is thought to be related to tissue hypoxia, with the tumor outgrowing its blood supply (Chamlin et al., 2007). Ulceration is more commonly seen in large hemangiomas, those with segmental distribution, and those with mixed morphology with both superficial and deep components (Morelli et al., 1994; Mulliken et al., 1995; Chamlin et al., 2007). Areas of friction or those exposed to moisture for a long time, such as the lower lip, neck, intertriginous areas, and anogenital and diaper region, are at high risk of ulceration. Nearly one-third of all ulcerated hemangiomas are found in the diaper region (Kim et al., 2001). Various treatment modalities have been shown to be effective in treating ulcerated hemangiomas, but all ulcerated hemangiomas benefit from local wound care, and combination therapy is more effective than monotherapy (McCuaig et al., 2013). Treatment options

• Fig. 107.6 Painful ulcerated infantile hemangioma on the neck.

included topically administered brimonidine, 0.2% or timolol, 0.5%, topical antibiotics with mupirocin or metronidazole, pulsed dye laser treatment, and systemic therapy with propranolol. Topical analgesics can also be useful to minimize pain and discomfort (Cheng and Friedlender, 2016).

Disfigurement. In addition to the transient disfigurement, hemangiomas located on the central face, large hemangiomas, and those with a significant superficial component can predispose the affected child to permanent scarring. IHs involving the nasal tip are at risk of a bulbous nasal tip or a “Cyrano” deformity (Fig. 107.7). This is caused by splaying of the alar cartilage during the proliferative growth phase. Early intervention with initiation of propranolol therapy can preserve the contour of the nose (Perkins et al., 2014). If a persistent deformity develops, surgical debulking

may be needed. Similarly, IHs located on the lip are at risk of deformity and disruption of the natural contours of the lips in addition to being at high risk of ulceration and permanent scarring (Fig. 107.8; Yanes et al., 2016). Large hemangiomas of the central chest or hemangiomas involving the breast tissue in females can also be quite disfiguring, leading to permanent breast hypoplasia in some cases (Fig. 107.9; Theiler et al., 2016). Disfigurement alone, regardless of threat to function, is a reasonable indication for medical therapy in certain cases and should be considered. Regression of hemangiomas does not always ensure complete normalization of the underlying skin and therefore can lead to lifelong psychosocial and emotional sequelae experienced by both the family and the patient (Zweegers and Van der Vleuten, 2012).

• **Fig. 107.9** Infantile hemangioma of the breast involving the nipple and areola.

Functional Complications

Periocular Hemangiomas. Hemangiomas located on the lid or around the orbit are at risk of causing visual impairment and can lead to amblyopia in severe cases. Amblyopia can be caused by direct pressure on the globe, causing astigmatism or myopia, or because of the size of the hemangioma there can be visual axis obstruction or strabismus (Spence-Shishido et al., 2015). Larger and segmental hemangiomas in the periorbital area pose the greatest risk of ocular complications. Deep retrobulbar IHs may present with proptosis and can also cause strabismus and visual acuity changes. Deep and mixed infant hemangiomas can also cause tear duct obstruction and exposure keratopathy. Aggressive and early initiation of treatment along with evaluation by a pediatric ophthalmologist can help prevent some of these complications (Spiteri Cornish and Reddy, 2011; Xue and Hildebrand, 2013). Further imaging, such as MRI, may be needed to assess the extent of the hemangioma or the presence of a deeper component.

Auricular Hemangiomas. With infantile hemangiomas of the ear there is high risk of physical deformity of the ear, cartilage destruction, ulceration, potential infection when ulceration is present, and potential hearing alterations. Segmental hemangiomas in this region have a higher rate of complications, and with them there can also be a risk of sensorineural and conductive hearing loss.

Potential Life-Threatening Complications

Airway Hemangiomas. Airway obstruction by an infantile hemangioma is a life-threatening complication that requires immediate evaluation and treatment. Airway hemangiomas can occur with or without the presence of cutaneous IHs. The highest risk occurs with hemangiomas located in a “beard distribution” specifically involving the left or right preauricular areas, chin, lower lip, and anterior part of the neck (Orlow et al., 1997). Involvement with IHs at four or more of these sites is associated with a 63% risk of a symptomatic airway hemangioma. A greater number of lesions in the beard distribution leads to a higher risk of airway involvement. Segmental hemangiomas involving facial segment 3 have a 29% risk of airway involvement. Clinically, airway hemangiomas present most commonly between 6 and 12 weeks of age with biphasic stridor or a hoarse, croup-like cry. The subglottis is the most common site of involvement, but the oral cavity, oropharynx, hypopharynx, larynx, and upper trachea can also be involved. Referral to a pediatric otolaryngologist is important for evaluation of the airway, and systemic treatment should be started immediately (O et al., 2009). Treatment of airway hemangiomas may require a combination of multiple medical and surgical treatments depending on the extent of involvement, which may include propranolol, oral and intralesional corticosteroids, vincristine, interferon alpha, surgical excision, and laser therapy.

Hepatic Hemangiomas. The presence of an IH in the liver can lead to potential serious complications such as congestive heart failure and consumptive hypothyroidism. Individuals with five or more cutaneous IHs (Fig. 107.10) of any size and in any location should be screened for the possibility of a hepatic IH (Horii et al., 2011). This study showed that in patients with five or more cutaneous hemangiomas, 16% of them had evidence of a hepatic hemangioma versus none in the group with fewer than five cutaneous hemangiomas. Individuals with large or segmental IHs do not seem to be at greater risk of hepatic IHs (Boon et al., 1996a; Horii et al., 2010).

Parotid Hemangiomas. Parotid hemangiomas can be isolated to the parotid gland or can be present as part of a segmental IH in the maxillary distribution of facial segment 3. Parotid

• **Fig. 107.10** Diffuse hemangiomatosis presenting with multifocal infantile hemangiomas on the skin and in the liver.

hemangiomas have a unique pattern of growth as they can have a longer proliferative growth phase than typical IHs. This can lead to longer treatment courses (Brandling-Bennett et al., 2008). They have also been associated with functional complications relating to deformity of adjacent structures such as the ear and lip and conductive hearing loss caused by narrowing of the external auditory canal. Life-threatening complications can also arise, including an association with subglottic hemangiomas, and less commonly congestive heart failure and consumptive hypothyroidism (Greene, 2004; De Corti et al., 2015).

Treatment

Most IHs are uncomplicated and spontaneously regress, but there is a subset of approximately 10%–15% of IHs that result in complications requiring treatment (Mulliken et al., 1995; Hoeger et al., 2015). Treatment is indicated in cases complicated by disfigurement or risk of disfigurement, ulceration, or functional compromise. There are various treatment modalities, including topical or systemic medications, surgery, or laser therapy, that are chosen on the basis of various factors, including the stage of growth, location, potential complications, and associated conditions. The various treatment modalities are outlined in the following sections. In general, pharmacologic treatment is the first-line treatment, with surgical and laser therapies being considered as adjunctive or second-line treatment following medical interventions.

Active Nonintervention. For most lesions the initial treatment of choice is “active nonintervention.” This is reserved for hemangiomas that are not at risk of causing disfigurement, ulceration, or causing any functional impairment. These often tend to be small focal hemangiomas in nonfacial locations. Anticipatory guidance should be discussed with the family in regard to the natural course of IHs and the initial period of rapid growth in the first few months of life and then slow rate of involution over many years. Demonstration of before-and-after photographs of growing and involuted hemangiomas in other children can help demonstrate the natural course and diminish parental concern. There is also a common concern of risk of significant hemorrhage. This is rare in IHs. Minor episodes of bleeding can result from trauma and respond to short-term compression, like any superficial wound.

Although the large majority of IHs do not require treatment and spontaneously regress, the disfigurement associated with the residua of IHs should not be underestimated, and treatment should be considered on the basis of the location and size of the infantile

hemangioma. Up to 40% of hemangiomas leave permanent skin changes that can be disfiguring (Enjolras and Mulliken, 1993). Psychological and social problems may result from facial or other visible deformities. A small study found that patients with untreated involuted facial hemangiomas had higher levels of social anxiety and decreased social initiative as compared with children with treated facial IHs (Costa et al., 2016). Therefore early intervention should be considered for lesions with a higher potential for complications.

Topical Therapies. Topically administered timolol maleate is a nonselective β -adrenergic receptor blocker that was first reported to be used in IHs in 2010 and has been shown to be most effective for superficial and thin hemangiomas (Püttgen et al., 2016). It is approved for use in pediatric glaucoma, but its use topically on the surface of the IHs is off-label. The preferred formulation is timolol gel forming solution, 0.5%. In general, timolol is well tolerated, without significant systemic side effects. However, a recent prospective study showed systemic absorption with use of one drop twice a day—although the concentrations detected were below 0.2 ng/mL, which is below the level at which systemic effects may begin to be seen (Weibel et al., 2016). Caution should be used in preterm infants with postmenstrual age less than 44 weeks and low birth weight infants weighing less than 2500 g at the time of initiation of treatment as there have been a few case reports of symptomatic bradycardia in this group (Frommelt et al., 2016). However, in these reported cases, the doses of timolol being used exceeded 0.2 ng/mL, and the treatment areas had variable or increased absorption (e.g., thin-skinned areas such as eyelid, mucosal surfaces, and ulcerated sites). Absorption within mucosal sites and ulcerated hemangiomas is variable, and therefore caution should be used, but there have been reports of use in these areas without any adverse side effects (Cante et al., 2012).

Systemic Therapies

Propranolol. Propranolol is a nonselective β -adrenergic receptor blocker that in 2008 was discovered by chance to treat IHs (Léauté-Labrèze et al., 2015; Sans et al., 2009). It had been used at higher doses in children with cardiac disease for many decades previously. In 2014, Hemangeol (propranolol hydrochloride, Pierre Fabre, Parsippany, New Jersey, United States) was approved by the US Food and Drug Administration as the only approved systemic treatment for IHs, and propranolol become first-line systemic treatment for IHs. The dosages for IHs range from 1 to 4 mg/kg per day in divided doses (two or three times daily), with a 98% response rate at a mean dosage of 2.1 mg/kg per day (Marqueling et al., 2013). There have now been three randomized controlled trials (Hogeling et al., 2011; Léauté-Labrèze et al., 2013, 2015) examining the efficacy of propranolol for IHs, with the largest trial showing the highest efficacy at dosages of 3 mg/kg per day for a 6-month course (Léauté-Labrèze et al., 2015). Despite this, most practitioners use maintenance dosages of 2 mg/kg per day because dosing regimens of more than 2 mg/kg per day did not show a significant increase in effect but did show an increase in the rate of adverse events (Wedgeworth et al., 2016). The most common adverse side effects of the medication reported are gastrointestinal disturbance, sleep disturbance, and acrocyanosis. These side effects were overall mild and reversible. Serious adverse effects such as symptomatic hypotension, hypoglycemia, bradycardia, and bronchospasm occurred infrequently and in a randomized control trial were reported at a similar frequency in the placebo group (Léauté-Labrèze et al., 2015). Once the medication is discontinued, rebound growth can occur, but this was more likely if the hemangioma was treated for less than 9 months versus a course of 12 to 15 months (Shah et al., 2016).

Corticosteroids. Oral corticosteroids were the first-line treatment before the discovery of propranolol. Prednisone or prednisolone dosages of 2 to 5 mg/kg per day were used, with the most optimal effects reported at a dosage of around 3 mg/kg per day (Esterly, 1995; Mulliken et al., 1995). Within 1 to 2 weeks, 30% of hemangiomas would show a dramatic response, but 40% would respond equivocally. Many side effects were noted in these patients, most notably cushingoid appearance, gastroesophageal reflux, insomnia, irritability, transient growth retardation, hyperglycemia, and rarely adrenal insufficiency, hypertension, and osteoporosis. Studies comparing propranolol with oral corticosteroids showed that clinical response to propranolol was more rapid and effective, with need for fewer surgical interventions, and that overall propranolol was better tolerated (Bertrand et al., 2011). Corticosteroids as a monotherapy are no longer used for IHs but rather are now reserved for complex and refractory cases and can be used in conjunction with propranolol or other therapies (Ranchod, 2005).

Intralesional corticosteroid injections may be used in small, localized hemangiomas in cosmetically sensitive areas with high rates of morbidity such as the lip, nasal tip, and eyelid (Couto and Greene, 2014; Herlihy et al., 2016). This can be used as a therapy adjuvant to other topical or systemic treatments. Complications include cutaneous atrophy, skin necrosis, and, for intralesional periocular injections, ophthalmic artery occlusion and blindness. Thus periocular intralesional steroid injection should be performed only by experienced pediatric ophthalmologists.

Other Therapies. Historically, interferon alpha and vincristine were used with variable effect for treatment of IHs. These therapies have potential adverse effects and are now reserved only for refractory lesions (Barlow et al., 1998; Wörle et al., 1999; Perez Payarols et al., 1995). Orally administered sirolimus, a mammalian target of rapamycin (mTOR) inhibitor, has now been considered in a few such cases (Kaylani et al., 2013).

Surgical Therapies

Laser Therapy. Pulsed dye laser treatment has been used in various settings with IHs. There have been some controversial data regarding its use as a monotherapy for uncomplicated hemangiomas, and it seems to be more efficacious when used in conjunction with propranolol or timolol (Asilian et al., 2015). It has also been used to heal ulcerations (David et al., 2003) and to decrease residual erythema and telangiectasias in an involuting hemangioma. However, a randomized prospective controlled trial of 121 infants found that pulsed dye laser treatment in uncomplicated hemangiomas is no better than watchful waiting (Batta et al., 2002). Pulsed dye laser treatment cannot prevent the preprogrammed growth pattern of hemangiomas and has a limited role during the proliferative phase. One risk of laser use during the proliferative phase can be ulceration. In contrast, it can be useful during involution, if there is residual redness or telangiectasias, which may be resolved faster than with the natural course of involution, but has no effect on fibrofatty residuum.

Surgical Excision. Surgical excision can be done in cases of medically refractory hemangiomas that are symptomatic and proliferating, in an emergency situation where there is life-threatening functional compromise, or in situations with recurrent profuse bleeding. It may also be beneficial in situations where there is a large disfiguring pedunculated lesion that will leave behind significant fibrofatty residual or scar.

Wound Care. Ulceration is a therapeutic challenge, but all ulcers benefit from local wound care and potential occlusive dressings. The type of dressing chosen depends on the amount of exudate

**TABLE
107.3****Indications for Work-Up of Extracutaneous Anomalies Associated With Infantile Hemangiomas**

| Clinical Presentation of Hemangioma | Association | Evaluation |
|---|---|---|
| Large facial hemangioma/segmental facial hemangioma >5 cm | PHACE syndrome | MRI/MRA of the brain and neck, echocardiogram, ophthalmology evaluation |
| Multifocal hemangiomas ≥5 cm | Extracutaneous hemangiomas, especially hepatic hemangiomas | Abdominal ultrasound examination with Doppler imaging |
| Periocular hemangioma | Ocular complications | Ophthalmology evaluation |
| Parotid hemangioma | Consumptive hypothyroidism, congestive heart failure, airway hemangioma | |
| Lumbosacral hemangioma >2.5 cm | LUMBAR syndrome | MRI of lumbar spine and pelvis, neurosurgical evaluation |
| Large lower trunk or lower extremity hemangioma | PELVIS syndrome | MRI of lumbar spine and pelvis, neurosurgical evaluation, urologic evaluation |
| Beard distribution hemangiomas | Evaluation for respiratory distress | Otolaryngology evaluation and MRI of the neck |
| Breast hemangioma/large segmental chest hemangioma | Breast hypoplasia | Consider systemic treatment |
| Midline hemangiomas (with other cutaneous markers) | Spinal dysraphism | Spinal ultrasound examination at <3 months of age, MRI of the spine |
| Segmental proximal upper extremity hemangioma with extension onto the chest | PHACE syndrome or cardiac abnormality | Echocardiogram |

MRA, Magnetic resonance angiography; MRI, magnetic resonance imaging.

and on the location of ulceration. For sites that are difficult to dress, frequent and liberal application of petrolatum jelly is effective. Various dressing materials, including petrolatum-impregnated gauze and seaweed-derived alginate dressings, are often recommended. Off-label use of becaplermin gel, a recombinant human platelet-derived growth factor, has reportedly shown dramatic healing in a small case series. The product now carries a warning from the Food and Drug Administration, which must be taken into consideration before its use (Metz et al., 2004; Yan, 2008). Agents for pain control should be considered, including topical anesthetics (being mindful of the percentage of body surface area covered) and oral analgesics such as acetaminophen or ibuprofen. A high index of suspicion should be maintained for secondary infection, with appropriate use of topical or oral antibiotics as needed. If conservative therapy is unsuccessful, pulsed dye laser treatment may relieve pain and speed reepithelialization (Achauer and Vander Kam, 1991; Morelli et al., 1991, 1994). The ulcers will heal but will inevitably leave scars.

Work-Up and Associations. A complete list of associations and the work-up needed for specific hemangiomas on the basis of their size and location is given in Table 107.3. Here we will highlight a few other special circumstances.

Visceral Involvement/Hepatic Hemangiomas. Diffuse neonatal hemangiomatosis (see Fig. 107.10) manifests itself as widely scattered, small superficial hemangiomas. Infants with this pattern of cutaneous involvement may have lesions limited to the skin, known as *benign neonatal hemangiomatosis*. However, associated hemangiomatosis of the liver, gastrointestinal tract, lungs, and/or central nervous system (CNS) can be complicated by visceral hemorrhage, hepatomegaly, high-output cardiac failure, or unexplained anemia or thrombocytopenia, with a significant mortality rate (Byard et al.,

1991). Congestive heart failure can also occur with a large, isolated hepatic hemangioma (Mulliken et al., 1995).

Segmental Hemangiomas

PHACE Syndrome. PHACE syndrome is characterized by a large (>5 cm) segmental hemangioma of the face, scalp, or neck with associated anomalies and developmental defects (Frieden et al., 1996). The acronym PHACE is used to describe the constellation of anomalies related to this syndrome: posterior fossa malformations, hemangioma, arterial anomalies, cardiac anomalies/coarctation of the aorta, and eye abnormalities. Midline defects such as sternal cleft and supraumbilical raphe can also be seen, and therefore sometimes this disorder is referred to as *PHACES*. The diagnostic criteria for PHACE syndrome were formalized by a consensus panel, and clinical features were grouped into major criteria. Definitive diagnosis of PHACE syndrome requires a facial segmental IH or an IH larger than 5 cm on the face or scalp in addition to one major or two minor criteria (Metry et al., 2009). This was revised in 2016 to also include a segmental hemangioma of the neck, upper trunk, or trunk and proximal upper extremity plus two major criteria (Garzon et al., 2016). The exact incidence of PHACE syndrome is unknown, but it may be more common than Sturge-Weber syndrome (SWS) (Metry et al., 2006). There is a striking female predominance in PHACE syndrome, with a female-to-male ratio of 9:1. A prospective study for PHACE syndrome found that 31% infants with facial IHs with a surface area of 22 cm² or greater met the PHACE diagnostic criteria, which is based on expert consensus, and approximately 90% of affected infants had more than one extracutaneous finding (Haggstrom et al., 2010). Children with frontotemporal and frontonasal IHs (known as segments 1 and 4) have a higher correlation with structural cerebral and cerebrovascular anomalies. Those with

mandibular (segment 3) or beard distribution lesions are at higher risk of cardiac abnormalities and IHs in the airway (Waner et al., 2003). The maxillary face (segment 2) appears to be a lower-risk segment for association with PHACE syndrome. The most common and potentially devastating sequelae of PHACE syndrome are neurologic, including structural brain anomalies and abnormalities of cerebral vasculature. Progressive stenoses and occlusions of cerebral arteries can also be seen. Both moyamoya-like vasculopathy and arterial ischemic strokes have been reported (Drolet et al., 2006; Heyer et al., 2006). Other comorbidities have recently been reported in patients with PHACE syndrome, including headaches, endocrine abnormalities, hearing abnormalities, speech delay, dysphagia, and dental anomalies (Garzon et al., 2016).

Because of the associated anomalies, patients suspected of having PHACE syndrome require the following:

- Echocardiogram to assess the patient for coarctation of the aorta or other structural cardiac abnormalities with possible cardiac MRI/magnetic resonance angiography (MRA) if the echocardiogram is abnormal
- MRI with contrast medium and MRA of the head and neck evaluating the patient for cerebrovascular and structural anomalies
- Ophthalmology examination of the retina
- Complete physical examination with particular focus on ventral midline defects
- Additional studies as indicated on the basis of signs and symptoms

LUMBAR/SACRAL/PELVIS Syndrome. Similarly to PHACE syndrome, large hemangiomas of the lower body may be associated with underlying structural abnormalities. Sacral and lumbar hemangiomas may reveal spinal dysraphism, including tethered spinal cord, lipomyelomeningocele, imperforate anus, renal anomalies, or abnormal external genitalia (Tavafoghi et al., 1978; Albright et al., 1989; Goldberg et al., 1986; Laurent et al., 1998). Many acronyms have been coined, all describing a similar entity of a segmental hemangioma in the lumbosacral or perineal region with associated regional abnormalities. These include LUMBAR, SACRAL, and PELVIS (Girard et al., 2006; Stockman et al., 2007; Iacobas et al., 2010).

Exact diagnostic criteria have not yet been defined, but IHs in the lumbosacral or perineal area that are large, midline, segmental, or present with other cutaneous markers (i.e., lipoma, gluteal cleft deviation, skin tag, aplasia cutis) should be screened for underlying abnormalities. One prospective study noted that 35% of patients with lumbosacral hemangiomas larger than 2.5 cm had evidence of spinal dysraphism on MRI (Drolet et al., 2010). Segmental hemangiomas in the lumbosacral region typically present with minimal or absent growth and persist as a patch with coarse telangiectasias, which can lead to delays in diagnosis. These are also at high risk of ulceration.

Congenital Hemangiomas. Congenital hemangiomas are an uncommon and distinct type of vascular proliferation that are fully formed at birth. They do not undergo the characteristic proliferative growth pattern in postnatal life as seen with IHs, but rather their proliferative phase occurs in utero. They are also GLUT1 negative, unlike IHs. Congenital hemangiomas can be divided into three major subtypes of rapidly involuting congenital hemangiomas (RICHs), noninvoluting congenital hemangiomas (NICH), and partially involuting congenital hemangiomas (PICHs) on the basis of their clinical progression. Congenital hemangiomas are usually solitary in nature and are more common on the extremities and head and neck (Boull and Maguiness, 2016).

Rapidly Involuting Congenital Hemangiomas. RICHs can present clinically in three distinct ways: (1) a raised violaceous tumor with prominent peripheral vasculature, (2) a raised tumor with coarse overlying telangiectasias with a peripheral halo of vasoconstriction or pallor, or (3) a pink-purple tumor with deep infiltrative nodules. There can sometimes be overlying hypertrichosis (Boon et al., 1996b). Rapid involution often begins in the first few weeks of life and is completed by 14 months of age. After involution there may be some residual atrophy, telangiectasias, persistent and prominent vessels, or milia present. There is a rare subtype of RICH where complete involution occurs in utero called *RICH fetal involution type*. Complications of RICHs are that they can undergo ulceration and bleeding shortly after birth, which can be painful and leave a permanent scar in the area of ulceration. There have also been reports of transient coagulopathy with thrombocytopenia that can occur. The decrease in platelet count is brief and not progressive as seen in KMP. The presence of this phenomenon can lead to misdiagnosis of RICH with tumors associated with KMP, such as tufted angiomas and kaposiform hemangioendothelioma, and therefore biopsy may be required to confirm the diagnosis.

Noninvoluting Congenital Hemangiomas. NICHs (Fig. 107.11) present as vascular patches, plaques, or nodules with blue or pink-purple color with overlying coarse telangiectasias and peripheral rim of pallor and vasoconstriction (Lee et al., 2014). They persist over time and grow proportionally with the child, without spontaneous regression. Some can become more protuberant or develop an increase in draining veins over time. Symptoms may develop during pregnancy or puberty, most notably that of pain (Lee et al., 2014).

Partially Involuting Congenital Hemangiomas. There is a small subset of congenital hemangiomas that begin a phase of involution that lasts until 12 to 30 months of age, at which time the involution halts (Nasseri et al., 2014). The residual vascular lesion then persists lifelong morphologically, resembling a NICH. There have been no reported complications in patients with PICH. The existence of PICH suggests that all congenital hemangiomas may exist along a spectrum.

Kaposiform Hemangioendotheliomas and Tufted Angiomas. Kaposiform hemangioendotheliomas (KHEs) and tufted angiomas are rare vascular tumors with locally aggressive and benign growth potential, respectively. They are thought to exist along a spectrum and are associated with life-threatening KMP. KMP is a profound and life-threatening thrombocytopenia that results from intralésional platelet trapping with a consumptive coagulopathy evidenced by elevation of D-dimer levels, reduction in fibrinogen

• **Fig. 107.11** Noninvoluting congenital hemangioma presenting as an unchanged vascular plaque in a 1-year-old. There are coarse telangiectasias with a blue background and surrounding vasoconstrictive halo.

levels, and prolongation of prothrombin time and partial thromboplastin time. The severity of the coagulopathy is variable.

Tufted angiomas (Fig. 107.12) typically present in infancy or early childhood as a solitary dusky erythematous indurated vascular plaque with overlying hypertrichosis, hyperpigmentation, and/or telangiectasias (Herron et al., 2002; Osio et al., 2010). Tufted angiomas tend to not be as aggressive and do have as deep infiltration as their counterpart kaposiform hemangioma. Spontaneous regression has been reported in some congenital cases or cases with earlier onset (Browning et al., 2006).

KHE presents as a solitary ill-defined red-purple plaque during infancy or early childhood. It can extend to involve the viscera, chest wall, and retroperitoneum and may present without cutaneous findings. KHE is more commonly seen in neonates and infants as compared with older children and may be associated with an increased risk of KMP (Gruman et al., 2005).

Pyogenic Granulomas. Pyogenic granulomas, also known as *lobular capillary hemangiomas* because of their histologic appearance, are benign acquired vascular tumors that are commonly seen in infants and children (Patrice et al., 1991; Fig. 107.13). They have also been seen to develop within an existing port-wine stain. They present clinically as a rapidly growing solitary, red papule that can

sometimes be exophytic or pedunculated in nature. They often present with a crusted or eroded surface because of their friable nature. They do not spontaneously involute, and treatment is often pursued because of recurrent episodes of bleeding and their friability. Treatment options include simple curettage or shave excision with electrocautery of the base, which is most definitive and curative. Other treatment options include topical therapies, such as topically administered timolol therapy, a beta blocker, or imiquimod therapy, or pulsed dye laser treatment, which have variable success with prolonged treatment courses. Recurrence is possible.

Vascular Malformations

Nevus Simplex

Nevus simplex, also known as a *salmon patch* or *fading capillary stain* and colloquially referred to as *angel's kiss* when it occurs on the forehead or eyelids and as *stork bite* when it occurs on the nape of the neck, is a very common capillary malformation that almost always spontaneously fades by 1 to 2 years of age (Fig. 107.14), although some malformations persist, most notably those at the nape of the neck (Fig. 107.15). It typically presents as a bilateral and symmetric faint pink patch with a feathery border and a

• **Fig. 107.12** Tufted angioma without Kasabach–Merritt phenomenon on the foot of a 4-month-old child. This was confirmed by biopsy.

• **Fig. 107.14** Nevus simplex on the glabella, nose, and eyelids of a newborn presenting as faint pink patches with feathery borders.

• **Fig. 107.13** Pyogenic granuloma on the cheek of a 8-month-old infant presenting as a bright-red glistening papule.

• **Fig. 107.15** Nevus simplex on the posterior occiput. Nevus simplex in this location can often persist.

midline predilection and most commonly occurs on the central forehead, glabella, upper eyelids, nose, upper lip, nape of the neck, posterior occiput, and the lower back. Nevus simplex located the midline in the lumbosacral area is usually a benign finding in isolation and not associated with underlying spinal dysraphism, but if there are any other cutaneous findings in this area (i.e., lipoma, hypertrichosis, faun tail, aplasia cutis) or abnormalities noted (i.e., gluteal cleft deformity), then further work-up is warranted. Prominent and persistent nevus simplex can be associated with underlying syndromes such as Beckwith–Wiedemann syndrome, macrocephaly–capillary malformation syndrome, and Nova syndrome (Burns et al., 1991; Table 107.2).

Capillary Malformation (Port-Wine Stain)

The terms *capillary malformation* and *port-wine stain* are used synonymously in the literature and refer to collections of malformed and ectatic dermal capillaries that persist over time (Fig. 107.16). They are present at birth and occur in 0.3% of neonates. They present as fairly well-demarcated red or pink patches that are often asymmetric, occur anywhere on the body, and may or may not be associated with localized overgrowth. They grow proportionally to the individual's somatic growth and over time can gradually darken from pink red to a darker red and deep purple. They also tend to thicken over time, developing a papulonodular surface change and can develop localized soft tissue or even bony hypertrophy. Nodular vascular growths called *pyogenic granulomas* (see earlier) can also develop within the existing port-wine stain and may require therapeutic intervention.

Port-wine stains can occur in isolation but also can be related to an underlying genetic disorder (Table 107.2). Of these syndromes, SWS is the most common. SWS is a sporadic neurocutaneous syndrome characterized by facial capillary malformation most commonly involving the upper face and forehead, leptomeningeal vascular malformation that can lead to seizures, hemiparesis, developmental delay, malformations of the choroid, and ophthalmologic abnormalities, most commonly glaucoma. SWS occurs in less than 30% of infants with facial port-wine stains. The risk is increased in infants with more extensive CMs of the face, notably those that have hemifacial or median forehead patterns of

involvement, previously thought to be located in the V1 trigeminal region. Patterns associated with SWS are now thought to correlate with patterns of mosaicism coined by Happle and Assim (2001) rather than trigeminal nerve distribution.

The degree of CNS involvement is variable in SWS, ranging from subclinical lesions to intractable seizures and intellectual impairment. Patients can still be at risk of glaucoma without SWS when the port-wine stain involves the forehead or upper or lower eyelid, V1 or V2 trigeminal pattern; therefore complete ophthalmologic examination is indicated for affected infants. Both SWS and isolated CMs have been found to be due to an activating somatic mosaic mutation in the *GNAQ* gene (Shirley et al., 2013). In SWS this mutation is also found in affected brain tissue, which is not seen in patients with isolated CMs. It is hypothesized that earlier timing of the mutation can lead to more extensive neurocutaneous involvement.

Treatment of an uncomplicated CM is aimed at minimizing disfigurement. With time these lesions can thicken and develop irregular surface changes, often with friable nodules. Most of the published data on laser treatment of port-wine stains in children come from studies using a pulsed dye laser (Kelly et al., 2002). Children require an average of 4 to 10 pulsed dye laser treatments for maximal lightening. The best results have been seen in children younger than 4 years, with studies recommending earlier onset of therapy to achieve the best results. Some studies describe use of laser treatment in patients as young as 4 weeks. In younger age groups, 20% can expect 95% clearing (Goldman et al., 1993). Pulsed dye laser therapy is less effective for facial port-wine stains that are close to the midline or those on the extremities (Garden and Bakus, 1993; Renfro and Geronemus, 1993). Laser therapy can yield remarkable improvement for many port-wine stains, minimizing the emotional pain that accompanies facial disfigurement. Unfortunately, none of the currently available lasers is capable of permanently erasing port-wine stains in most patients. There are also reports of darkening of port-wine stains many years after effective lightening (Huikeshoven et al., 2007). Laser treatment with the 1064-nm neodymium-doped yttrium aluminum garnet (Nd:YAG) laser and the 755-nm alexandrite laser has also been described to penetrate deeper vessels in more refractory port-wine

• **Fig. 107.16** (A) Port-wine stain of the periocular area, forehead, and scalp. (B) Port-wine stain involving the posterior auricular scalp, neck, cheek, and ear.

• **Fig. 107.17** A venous malformation on the sole of the foot.

stains on the basis of the theory that the longer wavelength of the second laser may be able to better target deeper vessels (Jasim and Handley, 2007). Recently, the use of topically administered rapamycin (an mTOR inhibitor) in conjunction with pulsed dye laser treatment has been used for refractory port-wine stains, with the hypothesized mechanism being decreased angiogenesis after laser therapy (Marqués et al., 2015).

Venous Malformations

Venous malformations are slow-flow vascular malformations composed of ill-defined venous channels with abnormal vessel walls that lack smooth muscle cells. They are often evident at birth and present as soft, blue-purple tumors or plaques with tortuous vessels that increase in size with exertion or when in a dependent position (Fig. 107.17). Over time they may become symptomatic and larger with increased dilation of vessels. They may affect the skin, mucous membranes, subcutaneous tissue, muscles, and joints and can involve visceral organs. Most cases are sporadic, but familial cases have also been reported. Localized intravascular coagulation can occur within the venous malformation (VM) that leads to either formation of thrombi, which form into calcifications called *phleboliths*, which can be quite painful, or bleeding (Mazoyer et al., 2008). Glomuvenous malformations are a distinct subset of VMs that present more superficially as blue-purple cobblestoned plaques and nodules commonly located on the extremities. Glomus cells distinctly line the malformed veins. Familial cases caused by mutations of the glomulin gene (*GLMN*) are more common than sporadic cases.

Lymphatic Malformations

Lymphatic malformations (LMs) are slow-flow vascular malformations. They can be classified as microcystic when individual malformed channels are smaller than 1 cm and macrocystic (i.e., cystic hygroma) when individual channels are larger than 1 cm, combined, or rarely generalized. LMs are most often seen in the head and neck region and can cause life-threatening airway

• **Fig. 107.18** A superficial lymphatic malformation on the back presenting with characteristic hemorrhagic papules and vesicles.

compromise in neonates. They can occur as an isolated finding or can be seen in association with underlying syndromes (Table 107.2). Some isolated LMs and those related to overgrowth syndromes are caused by a mutation in the gene encoding phosphatidylinositol 4,5-bisphosphate 3-kinase, catalytic subunit alpha (*PIK3CA*) (Kirkorian et al., 2016). Therefore in some cases, rapamycin (the mTOR inhibitor also used for refractory port-wine stain) has been used as a medical therapeutic option. Other possible therapeutic interventions include surgical excision for localized lesions, sclerotherapy, and laser treatment with a pulsed dye laser and a long-pulse Nd:YAG laser for superficial lesions (Fig. 107.18).

Arteriovenous Malformations

Arteriovenous malformations (AVMs) are fast-flow vascular malformations that are characterized by direct shunting of blood between the arteries and veins with bypassing of the capillaries. AVMs may present as a capillary malformation on the skin with pulsatility and significant warmth. The formation of vascular blebs that can easily bleed may also be seen. They can present within the skin but also viscerally anywhere in the body. The head and neck region, including the brain, are common locations. AVMs can occur in isolation or in association with various genetic syndromes (Table 107.2). Recently, mutations in *RASAI*, associated with familial forms of AVMs, have been found in individuals with an AVM of an extremity (Parkes Weber syndrome) and in individuals with CM-AVM syndrome, where individuals present with multiple cutaneous CMs, many with a “thumb print”-like quality and potential AVMs in the brain and/or spine.

These lesions do not resolve spontaneously and are more likely to become larger and more symptomatic over time. Complications are related to the flow rate and extent of the lesion. Localized thrombosis and phlebitis occur in low-flow lesions; high-flow lesions can cause significant bleeding, destructive interosseous changes (Fig. 107.19), and high-output cardiac failure. Many centers now have collaborative multidisciplinary groups to help manage the

most complicated vascular malformations and vascular tumors, which typically require treatment by physicians in many specialties.

Lymphedema

Lymphedema is a term used to describe diffuse soft tissue swelling characterized by firm, pitting edema. Lymphedema can occur in the setting of anomalous lymphatic drainage. Congenital variants have been reported. Females are affected more frequently than males. The lower limbs are the most commonly affected sites, but other sites may also be involved, and rarely, chylothorax or ascites may be present. *Milroy disease* is an autosomal dominant condition that manifests itself with progressive lymphedema of the lower extremities. Lymphedema of the extremities also occurs in *Turner (XO) syndrome*. Disorders associated with lymphedema are listed in [Table 107.4](#).

• **Fig. 107.19** Arteriovenous malformation of the hand causing distortion and contracture of the hand.

Disorders of Pigmentation

Hypopigmented Lesions

Localized areas of hypopigmentation on the skin of the newborn may be isolated phenomena, or they may be markers of extracutaneous abnormalities. The degree of hypopigmentation and the distribution of the defect help distinguish among the different conditions. To properly evaluate a patient with hypopigmentation, a distinction must first be made between complete depigmentation and hypopigmentation. A depigmenting condition produces pure white lesions that are devoid of normal melanocytes. Even in fair-skinned infants the lesions can often be easily seen in ordinary daylight. This group of disorders includes tyrosinase-negative oculocutaneous albinism, piebaldism, and vitiligo, all of which are rarely seen in infancy. A hypopigmented lesion is often subtly lighter in color than the surrounding skin. Histologic examination reveals a normal number of melanocytes. In fair-skinned children these lesions may require Wood lamp illumination to become obvious. This group includes anomalies with a deficient amount of melanin or hemoglobin caused by vasoconstriction, causing pallor and decreased skin pigment. *Nevus anemicus* and *hemangioma precursors* are two examples of areas of pallor that result from diminished superficial blood flow. Here we will discuss disorders of cutaneous mosaicism presenting as patterned pigmentation on the skin.

Nevus Depigmentosus (Nevus Achromicus)

Nevus depigmentosus is an uncommon condition occurring in 0.4% of newborns ([Shih, 2007](#)). It presents as a well-demarcated hypopigmented patch with irregular borders that can involve a small isolated circular or rectangular area or a larger segmental region following the lines of Blaschko, which are embryonic lines of ectodermal cell migration ([Fig. 107.20](#)). The patches are not truly depigmented as the name suggests but actually have reduced melanin levels. *Nevus depigmentosus* is thought to be a form of cutaneous mosaicism and results in a postzygotic somatic mutation that leads to a population of cells with decreased melanogenesis potential. They usually present at birth or shortly thereafter and grow in proportion to the child's overall growth, thus maintaining its shape. They occur sporadically, with no familial pattern of inheritance. There have been case reports of seizures, cognitive delays, and ipsilateral extremity hypertrophy, but most affected individuals do not have any extracutaneous abnormalities ([Lernia, 1999](#)). Sometimes, lentigines can be seen within the hypopigmented area. These are thought to be areas within the nevus where there

TABLE 107.4

Hereditary Lymphedema Syndromes (Primary Lymphedema)

| Syndrome | Clinical Features | Genetics |
|---|---|---|
| Nonne–Milroy disease (primary congenital lymphedema) | Congenital lymphedema of the lower limbs. Associated with enlarged veins of the leg, hydrocele and recurrent cellulitis | Mutation in <i>VEGFR3</i> . Autosomal dominant |
| Meige disease/lymphedema–distichiasis (pubertal-onset lymphedema) | Most common type of lymphedema. Can be associated with distichiasis, yellow nails, ptosis, syndactyly, cleft palate, and cardiac septal defects | Mutation in <i>FOXC2</i> . Autosomal dominant |
| Hypotrichosis–lymphedema–telangiectasia | Lymphedema, sparse hair, and telangiectasias of the skin | Mutation in <i>SOX18</i> . Autosomal dominant |
| Hennekam syndrome (generalized lymphatic dysplasia) | Lymphedema and multiorgan involvement (intestinal lymphangiectasia, protein-losing enteropathy), developmental delay | Mutations in <i>CUBE1</i> (some cases). Autosomal recessive |

• **Fig. 107.20** Nevus depigmentosus presenting as a well-demarcated hypopigmented patch that tends to be circular or oval.

• **Fig. 107.21** Pigmentary mosaicism presenting as a segmental block-like hyperpigmented patch on the back of an infant.

is resolution of the mutation and a return of pigmentation (Bolognia et al., 1998).

Pigmentary Mosaicism

The term *pigmentary mosaicism* is representative of a group of heterogeneous disorders of hypopigmentation and/or hyperpigmentation that include hypomelanosis of Ito (incontinentia pigmenti achromians), linear and whorled nevoid hypermelanosis that present as unilateral or bilateral linear streaks and whorls of cutaneous pigment change oriented along the lines of Blaschko (Fig. 107.21). They can also present in a block-like or checkerboard pattern or a phylloid or leaf-like pattern. Affected individuals may have areas that are hyperpigmented or hypopigmented, or both. The pattern may be congenital or may become apparent within the first 2 years after birth.

This condition is a form of somatic mosaicism. Various extra-cutaneous abnormalities (CNS, ocular, cardiac, and musculoskeletal) (Alvarez et al., 1993; Devriendt et al., 1998; Dereser-Dennl et al., 2000; Tunca et al., 2000) have been reported in patients, but the vast majority of individuals have pigmentary changes confined only to the skin. CNS abnormalities, manifesting themselves as

seizures or developmental delay, most often present by the age of 2 years.

Ash Leaf Macules

Ash leaf macules are small oval areas of hypopigmentation, named for their similarity in size and shape to a leaflet from a European mountain ash tree. They are one of the few congenital markers for infants with tuberous sclerosis. Tuberous sclerosis complex is a disorder of autosomal dominant inheritance with variable clinical manifestations characterized by the development of benign and malignant tumors in a variety of tissues, including the skin, CNS, and kidney (Gomez, 1991; Janninger and Schwart, 1993; Schwartz et al., 2007). This disorder is discussed in further detail in Chapter 104.

Hyperpigmented Lesions

Brown lesions usually reflect an increased number of melanocytic cells or an excess amount of melanin. Brown coloration can also be associated with a thickened epidermis. Most congenital brown lesions are isolated and benign, but it is important to recognize that some of them are syndrome associated and others may be potentially life threatening.

Café au Lait Macules

Café au lait macules (CALMs) are well-demarcated, oval or round, light brown macules or patches that differ in size, ranging from several millimeters to several centimeters in diameter (Fig. 107.22). They are commonly noted at birth or during infancy but may present in childhood as well. They cannot always be distinguished from melanocytic nevus on clinical grounds, but histologic examination is diagnostic, showing increased melanin levels within the basal keratinocytes, without melanocyte proliferation. CALMs differ within different ethnic groups, with a higher number and prevalence seen in darker-skinned individuals. The prevalence of CALMs is approximately 2.7% in the general population, 2% in white infants, and up to 12% in African-American infants. Large or segmental café au lait patches can be seen in McCune–Albright syndrome (Schwindinger et al., 1992; Shenker et al., 1993; Smith and Kirk, 2002), and multiple CALMs in the neonatal period may be an isolated finding but should alert the physician to the possibility of an associated syndrome, especially when six or more are present (Box 107.1; Fig. 107.23). Six or more café au lait lesions measuring 0.5cm or greater in diameter in prepubertal children and 1.5cm or greater in diameter in postpubertal children

• **Fig. 107.22** (A) Café au lait patch on the abdomen presenting as a tan brown well-demarcated patch. (B) Two café au lait spots presenting on the lateral thigh as well-demarcated tan brown macules.

• **Fig. 107.23** Multiple café au lait spots presenting on an infant with neurofibromatosis type 1. The presence of six or more café au lait spots larger than 0.5 cm in diameter on an infant and larger than 1.5 cm in adolescents is suggestive of the possibility of neurofibromatosis type 1. The presence of only café au lait spots does not meet the criteria for definitive diagnosis.

should alert the practitioner of the possibility of neurofibromatosis type 1 (NF1). Presence of café au lait lesions alone do not fulfill NF1 criteria (Ricardi et al.; Lazaro et al., 1994).

Lentigines

Lentigines are small tan-to-dark brown macules that most commonly appear sporadically in adulthood. They may be distinguished from other pigmented lesions by histologic examination that reveals elongated rete ridges, an increased number of singly dispersed

melanocytes along the basal layer, and increased melanization of the basal keratinocytes. Multiple or congenital lentigines are features of several syndromes.

Congenital Dermal Melanocytosis (Mongolian Spots)

More than 90% of African Americans, 81% of Asians, and 10% of whites (Pratt, 1953) are born with blue-gray macule of infancy, formerly known as *Mongolian spots*. These are brown, gray, or blue macules and patches, most commonly located in the lumbosacral area, but they can occur anywhere on the body. The macules may be single or multiple and range in size from a few millimeters to several centimeters in diameter. They often fade within the first few years after birth. Extensive lesions have been mistakenly attributed to abuse. Histologically, blue-gray macule of infancy is a collection of spindle-shaped melanocytes located deep in the dermis. Malignant change has never been reported.

Nevus of Ota/Ito

Nevus of Ota is a unilateral blue or gray discoloration involving the orbital and zygomatic areas, following the ophthalmic and zygomatic branches of the trigeminal nerve, including the sclera and fundus (Fig. 107.24). It is a sporadic condition, but it occurs with the highest frequency in Asians, affecting up to 1% of individuals in Japan (Kopf and Weidman, 1962), and has a female predominance. The discoloration is detected at birth in 60% of cases. Glaucoma is a frequent complication, occurring in 10% of individuals. A similar lesion, located in the deltotracheus area, is called *nevus of Ito* (Fig. 107.25). Spontaneous resolution does not occur, and over time these lesions can darken, increase in size, and potentially thicken. Individuals with periorbital involvement should undergo ophthalmologic examination. A rare association with malignant melanoma and uveal melanoma has been reported. Successful treatment has been achieved with Q-switched laser devices—ruby, alexandrite, and Nd:YAG.

Melanocytic Nevi

The category of nevocellular nevi includes congenital or acquired nevomelanocytic neoplasms. Nevomelanocytes are dendritic cells of neural crest origin. Nevocellular nevi have traditionally been categorized by the histologic position of the tumor nests within

• **Fig. 107.24** Nevus of Ota on the lateral right cheek of a girl presenting as a blue-gray patch of discoloration.

• **Fig. 107.25** Nevus of Ito on the left arm of a child presenting as a blue-gray patch.

the skin. *Junctional nevi* are the most superficial, located at the junction between the epidermis and dermis. These lesions appear clinically as macules. *Intradermal nevi* are located deep to the dermoepidermal junction and are usually papular. “*Blue*” *nevi* are a variant located in the deep dermis, made up of cells that have elongated, neural features. *Compound nevi* have both junctional and dermal nests of nevomelanocytes. Melanocytic nevi can be further subdivided by their time of onset: congenital, early onset (before the age of 2 years), and acquired (Williams, 1993; Kovalyshyn et al., 2009).

• **Fig. 107.26** (A) Congenital melanocytic nevus with hypertrichosis, small size. (B) Large congenital melanocytic nevus involving the neck and back with multiple smaller “satellite” nevi on the arms and lower back.

Congenital Melanocytic Nevi

Congenital melanocytic nevi (CMN) are hamartomas derived from neural crest cells that form in utero and are most often present at birth or within the first year (Fig. 107.26). They are classified by the largest diameter of their adult projected size. On the basis of size classification, they are categorized as small (<1.5 cm), intermediate sized (1.5 to 19.9 cm), large (20 to 40 cm), and giant (>40 cm). Delineations are based on adult data. Conversion factors have been developed to help predict ultimate size: for CMN on the head, multiply size by 1.7; CMN on the lower extremities, multiply size by 3.3; and for CMN on the trunk, upper extremities, and feet, multiply size by 2.8 (Marghoob et al., 1996). On the basis of these classifications the estimated incidence of small and intermediate-sized CMN is approximately 1%–6%, that of large CMN is approximately 1 in 20,000, and that of giant CMN is approximately 1 in 500,000 (Price, 2016). Melanoma in small and intermediate-sized nevi tends to be approximately 1% lifetime risk or less, nearing the risk within the general population, with

most cases occurring after puberty. In large and giant CMN, the risk of melanoma development ranges from 4.5%–10% (Kopf et al., 1979; Gari et al., 1988; Kufflik and Janniger, 1994; Ozturkcan et al., 1994; Williams and Pennella, 1994; Marghoob et al., 1996; Richardson et al., 2002), with 70% of melanomas diagnosed before the age of 10 years. Other malignancies have also been reported to arise from CMN. These include rhabdomyosarcoma, liposarcoma, malignant peripheral nerve sheath tumors, and other sarcomas. In addition to cutaneous malignancy, large and giant CMN have been associated with the development of neurocutaneous melanosis (NCM), which is characterized by CNS proliferation of melanocytes (Kadonaga and Frieden, 1991). Symptomatic NCM manifests itself with signs or symptoms of increased intracranial pressure and carries a very poor prognosis, with an increased incidence of CNS melanoma (Frieden et al., 1994; Sandsmark et al., 1994). NCM often becomes symptomatic within the first few years after birth. MRI can aid in the diagnosis (Barkovich et al., 1994). Although initial reports emphasized thickening of the leptomeninges, the most common MRI sign of NCM is the spin–lattice (T1) nuclear magnetic relaxation time in the parenchyma of the cerebellum or anterior temporal lobes (sometimes accompanied by the spin–spin [T2] relaxation time). Radiologic identification of malignant degeneration is difficult. Roughly half of asymptomatic infants and children with giant CMN have evidence of NCM on MRI (Frieden et al., 1994). The presence of asymptomatic NCM does not necessarily bode a poorer prognosis, and NCM can continue to be present and asymptomatic throughout life. The term *CMN syndrome* has now been used to broaden the scope of NCM to include more extracutaneous manifestations associated with CMN. Patients with NCM are at risk of developing CNS melanomas, but this risk is significantly higher in individuals with symptomatic NCM. The risk of developing NCM has been correlated with the number of accompanying CMN, historically termed *satellite lesions*, with patients who have more than 20 such lesions carrying a five times greater risk of NCM.

Conservative management of large congenital nevi by surveillance alone is complicated by the presence of features that may fit the screening ABCDE criteria (asymmetry, border irregularity, color variegate, diameter >6 mm, evolution) for a lesion that is suggestive of melanoma. Most of these nevi have an irregular surface appearance from birth and are variably thickened, hairy, verrucous, or nodular. Smaller, widely scattered satellite lesions are almost always present, but there have been no reports of melanoma in satellite lesions. Extracutaneous lesions have also been detected in several sites, including the meninges, lymph nodes, and placental villi (Hara, 1993). Often these nevi have atypical histologic features as well. For children who develop malignant melanoma within a giant nevus, the prognosis is very poor. However, many of the lesions that have an alarming appearance at birth do not exhibit malignant behavior or produce widespread metastases or cause death. In fact, congenital melanoma is very rare and is associated with congenital nevi in less than 50% of reported cases (Williams and Pennella, 1994).

The management of CMN remains controversial, with advocates for and against prophylactic excision. Routine excision is generally not recommended and may not eliminate the risk of melanoma completely given the presence of melanocytes deep with the fascia. Surgical removal is never an easy option. Multiple procedures are usually required, with the attendant high risks of significant morbidity, sometimes yielding results that are more disfiguring than the birthmark. Procedures performed in early childhood, such as tissue expansion (Vergnes et al., 1993) and partial-thickness resection (Sandsmark et al., 1993), may improve the aesthetic outcome but

• **Fig. 107.27** Nevus spilus presenting as a tan patch with multiple darker brown macules and papules within the patch.

have associated stigma and pain. The efficacy of such approaches in the prevention of malignancy has never been documented, and it is unlikely to eliminate the risk of malignancy completely.

Nevus Spilus

Nevus spilus (speckled lentiginous nevus) is a hyperpigmented lesion that consists of focal proliferation of melanocytes along the basal layer of the epidermis (dark spots) within a café au lait spot in the background (Fig. 107.27). Nevus spilus is considered a distinct subtype of a congenital melanocytic nevus, with the associated risk of melanoma being lower than with traditional CMN. There are no other associated abnormalities.

Congenital Tumors of Epithelial Origin

Epidermal Nevus

Epidermal nevus may manifest itself in the newborn period as a smooth hyperpigmented patch or rough, skin-colored plaque, most often on the trunk or extremities, frequently oriented along the lines of Blaschko (Fig. 107.28). With time, epidermal nevi may enlarge, usually within the first few years after birth, and most become verrucous and hypertrophic over time. Treatment is difficult because recurrence is common after destruction or excision.

Nevus Sebaceous

Nevus sebaceous presents as an alopecic tan, yellow, to salmon colored plaque appearing most often on the scalp or face (Fig. 107.29). It may be nodular at birth and again after puberty, flattening during childhood. A variety of neoplasms, both benign and malignant, including basal cell carcinoma, develop in up to 15% of patients with sebaceous nevi. Development of neoplasms rarely occurs before puberty.

Like other mosaic disorders, epidermal and sebaceous nevi are believed to be localized manifestations of somatic genetic mutations that would be lethal if fully expressed. A subset of patients with epidermal nevi are genetic mosaics for an autosomal dominant form of ichthyosis called *epidermolytic hyperkeratosis* (or *bullous ichthyosiform erythroderma*) (Paller et al., 1994). These individuals may be at risk of having offspring with total body involvement.

The striking appearance of epidermal nevi has inspired descriptive nomenclature. *Nevus verrucosus* is a solitary plaque. *Nevus unius lateris* is an extensive linear lesion that is unilateral, following the lines of Blaschko. Both keratinocytic and sebaceous components may occur in the same patient, the former more commonly involving the trunk and extremities and the latter more often involving the head and neck. The term *ichthyosis hystrix* refers to extensive, bilateral involvement with epidermal nevus.

Skin biopsy will rule out other conditions, distinguish between epidermal nevus and nevus sebaceous, and detect the diagnostic histologic features of epidermolytic hyperkeratosis. Small epidermal nevi do not require treatment. Nevus sebaceous carries a small risk of malignant degeneration. It may be excised at any time, depending

on the size of the lesion, the benefits of surgical intervention versus the risks of anesthesia, and the preference of the patient and family but rarely becomes symptomatic or much of an issue until after puberty. Recent studies suggest that the risk of basal cell carcinoma, the most common malignancy to arise in nevus sebaceous, is closer to 1%, much lower than was reported in the past (Cribier et al., 2000).

There is no optimal therapy for larger lesions or those that are disfiguring. Full-thickness excision, including the subcutaneous tissue, is recommended to decrease the risk of recurrence. Laser therapy has been performed with ablative lasers, and there are a few reports suggesting that the Q-switched Nd:YAG laser holds some promise as another therapeutic option. Topically applied keratolytic agents may be palliative. Genetic counseling about the risk for offspring of fully expressed disease should be considered for individuals with epidermal nevi that reveal the histologic features of epidermolytic hyperkeratosis.

Epidermal (Linear Sebaceous) Nevus Syndrome

In less than 10% of affected people, epidermal nevi and sebaceous nevi (especially those involving the head) are associated with a variety of extracutaneous abnormalities, mainly ocular (in 33% of cases), neurologic (in 50%), and skeletal (in 70%), a condition referred to as *epidermal nevus syndrome*. Bone abnormalities include vertebral anomalies, kyphoscoliosis, limb shortening, and hemi-hypertrophy. CNS disorders include seizures, mental retardation, and hemiparesis; ocular abnormalities include eyelid/conjunctival nevus, coloboma, corneal opacity, and nystagmus. Malignancies also occur in this syndrome with a greater than expected frequency, including Wilms tumor, nephroblastoma, gastrointestinal carcinomas, and rhabdomyosarcoma (Marghoob et al., 1993).

Congenital Tumors of Dermal and Subcutaneous Origin

Juvenile Xanthogranuloma

JXG is a benign, self-healing, non-Langerhans cell histiocytic tumor of infancy (Fig. 107.30). JXG is derived from dermal dendrocytes

• **Fig. 107.28** Epidermal nevus presenting as verrucous tan brown papules coalescing in a curvilinear plaque.

• **Fig. 107.29** (A) Nevus sebaceous in an adolescent male presenting as a thickened yellow-pink alopecic plaque with wart-like changes. (B) Nevus sebaceous presenting as an alopecic plaque with verrucous or wart-like changes.

• **Fig. 107.30** (A) Juvenile xanthogranuloma with characteristic tan yellow color and rim of erythema in an infant. (B) Juvenile xanthogranuloma presenting as a yellow-orange papule.

and is present in normolipemic individuals without abnormalities in their lipid metabolism (Newell et al., 1973; Gianotti and Caputo, 1985; Hernandez-Martin et al., 1997). JXG may be congenital in approximately 30% of cases, with 75% presenting within the first year of life (Nomland, 1959). Early on, cutaneous lesions present as erythematous papules with minimal yellow-orange color. As they mature they become more characteristically yellow in color and may develop overlying telangiectasias. They often present on the head, neck, and trunk and can be categorized by their size: “micronodular” (<10 mm) and “macronodular” (>10 mm) forms and rarely giant JXG, which can be up to 5 to 10 cm in size. They may present as a solitary lesion or as multiple lesions, with the solitary presentation being most common, occurring in up to 90% of patients. JXG may also be rarely localized to the eye or mucous membranes (De Raeve et al., 1994). Skin biopsy is usually diagnostic, revealing characteristic foamy histiocytes and Touton giant cells within the dermis.

The vast majority of infants with JXG are otherwise healthy. Giant JXG can have an alarming appearance and may be confused with other types of histiocytic tumors (Magana et al., 1994). JXGs have two clinically significant associations. The first is ocular JXG and its associated complications. Less than 0.5% of children with skin lesions have ocular involvement, but half of children with ocular JXG have cutaneous lesions (Chang et al., 1996). Ocular examination in individuals younger than 2 years with multiple JXGs is recommended. Ocular tumors may manifest themselves as unilateral glaucoma, uveitis, heterochromia iridis, or proptosis, and ocular JXG is the most common cause of hyphema in infancy (Zimmerman, 1965; Gaynes and Cohen, 1967). The iris is the most frequently affected ocular tissue (Hamdani et al., 2000).

The second significant association is related to reports of a rare triad of JXG, juvenile myelomonocytic leukemia (JMML), and neurofibromatosis type 1 (NF-1). The appearance of JXG usually precedes the diagnosis of leukemia or occurs concurrently at the time of diagnosis, and there are often multiple JXGs (Cooper et al., 1984; Sherer et al., 1993). Routine screening for JMML is not recommended in NF-1 patients with or without JXG, but evidence of hepatosplenomegaly, lymphadenopathy, or pallor should prompt appropriate work-up (Burgdorf and Zelger, 2004). Fewer than 20 patients with intracranial JXG without cutaneous manifestations have been described (Schultz et al., 1997; Bostrom et al., 2000).

Most cases of JXG are asymptomatic and self-limited, but ulceration and bleeding of cutaneous lesions can occur. Giant lesions have a similar prognosis (Magana et al., 1994). Ophthalmologic evaluation is indicated for children who present in the first 2 years after birth with multiple lesions. Parents should be provided with anticipatory guidance about the ocular complications (Chang et al., 1996). JXG typically involutes within 3 to 6 years (Hansen, 1992). Cutaneous lesions can leave behind residual anetoderma, mild atrophy, and/or hyperpigmentation. Recurrence has been documented after surgical excision, a therapy that is indicated only for lesions that are frequently traumatized, symptomatic, or are more disfiguring than the resultant scar would be.

Mastocytosis

Mastocytosis comprises a group of disorders characterized by increased numbers of tissue mast cells (Fig. 107.31). The skin is the most common site of involvement, but the lymphoreticular system, gastrointestinal tract, and bone marrow also may be affected. Symptoms result from the local or generalized effects of the release of histamine and other mast cell mediators. Pruritus, edema, blistering, and flushing are common. Abdominal pain, diarrhea, and vomiting are unusual. Hypotension is rare (Kettelhut and Metcalfe, 1991). If rubbed or traumatized, skin affected by mastocytosis will develop a diagnostic wheal (Darier sign). The site may blister or become hemorrhagic in a neonate.

Urticaria pigmentosa is the name given to the most common form of mastocytosis in infants, featuring multiple, small (1 to 3 cm in diameter) papules usually located on the trunk. The disease may be congenital but usually manifests itself within the first 6 months after birth (Kettelhut and Metcalfe, 1991). A single, localized lesion is known as a *solitary mastocytoma*. These tumors can range in size from approximately 2 to 6 cm. Diffuse cutaneous mastocytosis is an unusual condition that may manifest itself at birth with widespread blistering or diffuse thickening of the skin. Systemic mastocytosis is more commonly seen in adults and is defined by multifocal lesions in the bone marrow or other extracutaneous organs, together with signs of systemic disease. It is further subdivided into indolent systemic mastocytosis, systemic mastocytosis with an associated clonal hematologic non-mast cell lineage disease,

• **Fig. 107.31** Solitary mastocytoma presenting as a tan brown plaque with characteristic peau d'orange (orange peel-like) surface change.

aggressive systemic mastocytosis, and mast cell leukemia (Valent et al., 2001).

The diagnosis may be confirmed by a skin biopsy, which reveals mast cell hyperplasia within the dermis. Aminocaproate esterase is the most specific enzyme marker for identification of mast cells. Immunohistochemical stains for tryptase and c-Kit are also sensitive and specific markers for mast cells (Li, 2001). Mutations in *KIT*, the gene encoding the receptor for stem cell factor, may play a significant role in the biology of mast cell malignancies (Gupta et al., 2002). Plasma histamine levels are elevated in most children with mastocytosis, sometimes to remarkably high levels. Further work-up for evidence of systemic involvement should be limited to pediatric patients with extracutaneous signs and symptoms or those who require general anesthesia (Kettelhut and Metcalfe, 1991).

Caregivers should be educated to avoid exposing infants to factors that trigger mast cell degranulation, such as friction, pressure, temperature extremes, and substances that promote mast cell degranulation (aspirin, alcohol, narcotics, amphotericin B, or iodine-containing contrast media). If general anesthesia is required, perioperative administration of histamine receptor blockers is recommended (Lerno et al., 1990).

For patients with limited skin involvement, application of potent topical corticosteroids may hasten involution of lesions. Symptomatic patients may benefit from a classic histamine H₁ receptor blocker such as hydroxyzine or cyproheptadine. An H₂ blocker, such as ranitidine, or orally administered disodium cromoglycate may be added in the presence of gastrointestinal symptoms. Hypotension requires corticosteroids in addition to H₁ and H₂ antihistamines and intensive supportive care. Solitary mastocytomas usually involute by school age. Lesions of urticaria pigmentosa typically resolve by puberty.

Connective Tissue Nevus (Connective Tissue Hamartoma)

Connective tissue nevi are hamartomas comprising dermal collagen, elastic fibers, or a combination of the two. They are benign lesions that can occur in isolation or in relation to a genetic syndrome

such as tuberous sclerosis or Proteus syndrome (Smith and Kirk, 2002). They present as flesh-colored dermal plaques that can be subtle on examination to hypertrophic with a cobblestoned and cerebriform appearance. They are usually asymptomatic and do not often require any intervention. Diagnosis is often made clinically, but if the diagnosis is unclear, a skin biopsy can be performed.

Neurofibroma

Neurofibromas are benign tumors that are composed of neuromesenchymal tissue. They appear as brown or red-brown soft papules or papulonodules. They often present in young adulthood, but there is a variant of a plexiform neurofibroma that can present earlier in infancy and can resemble a congenital melanocytic nevus. Neurofibromas can occur as isolated tumors in an association with an underlying genetic disorder, such as NF-1. They can be surgically excised if they become symptomatic or are cosmetically disfiguring.

Developmental Anomalies of the Skin

Developmental anomalies are present at birth and represent a heterogeneous group of disorders that are caused by a disruption in the formation of vital structures within the skin. They may occur in isolation or they may be a marker of extracutaneous abnormalities and thus require further evaluation.

Midline Anomalies

Congenital midline defects are a distinct group of diagnostically and therapeutically challenging conditions. These anomalies can be markers for potential neural tube dysraphism occurring at the cranial or caudal midline. These markers include dimples, sinuses, skin tags, capillary malformation, hemangiomas, nodules, lipomas, dermoid cysts or sinus, and midline circumscribed or annular hypertrichosis that may represent a marker for an underlying CNS problem or an intracranial connection (Hayashi et al., 1984; Martinez-Lage et al., 1992). A midline mass in the nasal area may represent a dermoid cyst or sinus, encephalocele, or glioma (Paller et al., 1991). Midline scalp lesions include aplasia cutis congenita, dermoid cyst or sinus, encephalocele, meningocele, and heterotopic brain tissue. The “hair collar sign” may mark ectopic neural tissue and underlying CNS malformations (Commens et al., 1989; Drolet et al., 1995). Biopsy of a midline mass should not be performed unless an imaging study, computed tomography, or MRI has been performed to help clarify the nature of the lesion and any intracranial connections, although small intracranial connections may still be missed. If the possibility of an intracranial connection exists, referral to a neurosurgeon is indicated (Martinez-Lage et al., 1992).

Markers of occult spinal dysraphism exist in the lumbosacral region and include various cutaneous midline lesions such as lipomas, skin tags, pseudotails and tails, dimples and sinuses, hypertrichosis, aplasia cutis congenita, dermoid cyst or sinus, pigmentary changes, hemangiomas, CMs, and telangiectasias. The presence of two or more stigmata indicates a higher risk of the presence of occult spinal dysraphism. Box 107.2 stratifies findings on the basis of their risk for occult spinal dysraphism (Sewell et al., 2015). There are no evidence-based guidelines for imaging recommendations for spinal dysraphism. In general, in high-risk situations, MRI is the preferred imaging modality but is limited by its cost, availability, and need for sedation. In infants up to 6 months old, high-resolution ultrasonography may be performed before the ossification of the vertebral bodies, but it has decreased sensitivity

• BOX 107.2 Risk Stratification of Markers of Occult Spinal Dysraphism

High Risk

- Two or more cutaneous stigmata
- Lipoma
- Acrochordon, pseudotail, true tail
- Aplasia cutis and congenital scars
- Dermoid cyst or dermal sinus
- Infantile hemangioma ≥ 2.5 cm

Intermediate Risk

- Atypical dimple >5 mm in diameter, >2.5 cm from the anal verge
- Infantile hemangioma <2.5 cm
- Hypertrichosis (faun tail or silky down)

Low Risk

- Hyperpigmentation or hypopigmentation
- Melanocytic nevi
- Simple dimple ≤ 5 mm in diameter, ≤ 2.5 cm from the anal verge
- Teratomas
- Port-wine stain (capillary malformation) or telangiectasias

(Modified from Sewell MJ, Chiu YE, Drolet BA. Neural tube dysraphism: review of cutaneous markers and imaging. *Pediatr Dermatol*. 2015;32:161–170.)

when compared with MRI and has large variability in accuracy depending on the person performing the study. If the ultrasound results are abnormal or inconclusive, MRI should be performed. It is suggested that simple dimples (Gibson et al., 1995; Robinson et al., 2005) and isolated low-risk lesions do not require a screening ultrasound examination (Guggisberg et al., 2004). On the neck a midline pit or nodule may represent a congenital midline cervical cleft (Eastlack et al., 2000) or thyroglossal duct cyst or sinus. A bronchogenic cyst or sinus cyst presents as a nodule or pit at the suprasternal notch at birth and is due to remnant respiratory epithelium. Branchial cleft anomalies, cysts, or sinuses do not present at the midline and are located in the preauricular region and lateral neck. They are at risk of infection and therefore can be surgically removed.

Preauricular Pits and Sinuses

Preauricular pits are common congenital abnormalities that present as small depressions or dells, often 1 to 3 mm in size located adjacent to the external ear, usually at the anterior margin of the ascending limb of the helix, but have also been reported along the lateral surface of the crus of the helix and the superior posterior margin of the helix, tragus, or lobule. There may be a sinus tract connected to the pit in the skin, in which case fluid or pus may drain from the opening. Preauricular sinuses are usually asymptomatic and isolated but can be multiple and bilateral in 25%–50% cases. The bilateral sinuses tend to be inherited in an autosomal dominant pattern. There have been associations with a few genetic syndromes as well (Box 107.3).

Preauricular sinuses are rarely associated with deafness or renal problems. Renal ultrasound screening is recommended only if there are other worrisome features present, such as the presence of dimorphic features, a family history of deafness, a maternal history of gestation diabetes, and auricular and/or renal malformations (Wang et al., 2001). Hearing impairment occurs at a higher rate in individuals with accessory tragi, and screening is

recommended if a newborn hearing screen was not performed (Roth et al., 2008). Symptomatic sinuses that drain fluid or become infected should be cultured and treated with appropriate antibiotics. If recurrent infection occurs, surgical excision by an experienced surgeon is recommended because the sinus can extend to the periosteum with the auditory canal (Scheinfeld et al., 2004).

Accessory Tragus

Accessory tragi, inaccurately referred to as *preauricular tags*, are relatively common congenital malformations of the external ear. They present as soft, flesh-colored pedunculated papules that can occur anywhere from the preauricular area to the angle of the mouth following the embryonic fusion line of the mandibular and maxillary branches of the first branchial arch (Fig. 107.32). They are present at birth and can be multiple and/or bilateral. In most

cases they occur as an isolated developmental defect, but association with other abnormalities of the first and second branchial arch or branchial arch syndromes can occur (Box 107.4; Bahrani and Khachemoune, 2014). Association with deafness and renal abnormalities is controversial. The renal ultrasound and hearing screening guidelines are the same as mentioned with preauricular pits and sinuses earlier. Accessory tragi can be limited to the dermis but can also contain cartilage or can be contiguous with the external ear canal. Therefore if surgical excision is performed, it should be done by an experienced surgeon. Suture ligation should not be done and can result in complications.

Congenital Cartilaginous Rests of the Neck (Cervical Tabs, Wattles)

Congenital cartilaginous rests of the neck, also known as *cervical tabs* or *wattles*, are present at birth and are formed from a remnant of the branchial arch or ectopic auricular tissue (Figs. 107.33–107.34).

• **Fig. 107.33** Congenital cartilaginous rests of the neck, aka *wattles*, presenting as a small flesh-colored papule on the anterior part of the neck.

• **Fig. 107.34** Cutis marmorata telangiectasia congenita.

They present as soft, flesh-colored papules or nodules that can occur anywhere on the neck but most commonly appear over the lower half of the sternocleidomastoid muscle. They may contain cartilage and can be multiple and bilateral. They do not have a deeper connection or sinus or tract associated with them and therefore do not require further imaging or treatment. Surgical excision could be considered, but largely for aesthetic purposes.

Supernumerary Digits (Rudimentary Polydactyly)

Supernumerary digits can range in their presentation from subtle small pedunculated papules to full-sized digits. They arise from the lateral surface of the normal digit and may occur on any digit, with the ulnar surface of the fifth finger being the most common site. They often contain cartilage, nerves, and nail. Therefore surgical excision with nerve dissection can be undertaken to remove these accessory digits. Ligation of the supernumerary digit without complete dissection of the nerve can result in a traumatic neuroma, skin necrosis, and infection (Frieden et al., 1995; Leber and Gosain, 2003).

Supernumerary Nipples (Polythelia, Accessory Nipples)

Supernumerary nipples can be found anywhere along the embryologic milk lines that course from the axilla to the inner thigh. They present as brown or reddish-brown pedunculated papules and are often bilateral. In the newborn period their clinical presentation is very subtle as a small light-brown macule. They may present with or without true extramammary tissue and mammary glands. They can be mistaken for melanocytic nevi, warts, neurofibromas, or acrochordons. Usually no further evaluation or treatment is necessary unless glandular tissue is present, in which case complete surgical excision is recommended because of enlargement at puberty causing pain and social stigma.

Median Raphe Cysts (Congenital Sinus and Cysts of Genitoperineal Raphe, Mucous Cysts of the Penile Skin, Parameatal Cysts)

Median raphe cysts present as small white to flesh-colored papules that can be found anywhere on the ventral penis, scrotum, and perineum in a midline position. They can be solitary or multiple. They are believed to result from congenital alterations in embryologic development of male genitalia and are due to incomplete closure of the urethral and/or genital folds or result from outgrowths of the embryologic epithelium after primary closure of the folds (Park et al., 2006). They are usually asymptomatic in most cases, and there have been reports of spontaneous regression over time. If they persist, become symptomatic, or infected, simple excision with primary closure can be undertaken (Krauel et al., 2008).

Eye and Vision Disorders

ALEJANDRA G. DE ALBA CAMPOMANES AND GIL BINENBAUM

KEY POINTS

- “Early visual experience drives the architecture of the visual brain.”
- Screening eye examinations are important in all infants, regardless of gestational age. All neonates should have an examination of the red reflex before discharge from the newborn nursery.
- The absence of visual responsiveness by 2 months of age should prompt an urgent ophthalmologic evaluation.
- Most full-term infants establish normal ocular alignment within the first 2 months.
- Nystagmus can be a manifestation of a congenital motor entity, secondary to visual pathway defects or neurologic disease. Nystagmus caused by defective vision does not develop until approximately 3 months of age.
- Successful treatment of congenital cataracts is highly dependent on early diagnosis and prompt referral.
- The successful management of retinoblastoma depends on the ability to detect the disease while it is still intraocular; disease stage correlates with delay in diagnosis.
- Neonatologists have both a clinical and a medicolegal responsibility to arrange timely diagnostic retinopathy of prematurity examinations for preterm babies in the neonatal intensive care unit and to communicate to parents the vital importance of keeping outpatient ophthalmology appointments.

The fast pace of development of the visual system in the neonatal period makes the recognition of ocular abnormalities extremely important. As early as 4 to 6 months after birth, some visual functions are permanently set and if impaired cannot be fully restored to normalcy. For example, a visually significant congenital cataract must be surgically addressed before the third month of life to avoid potentially irreversible vision loss. This urgency makes the neonatologist an invaluable player in the recognition and management of neonatal eye diseases. Screening eye examinations are important in all infants, regardless of gestational age and whether they occur in the neonatal intensive care unit (NICU), the newborn nursery, or the primary care provider's office. Healthcare professionals caring for newborns need to be familiar with indications for referral to a pediatric ophthalmologist, and in premature infants the added risk of retinopathy of prematurity (ROP) mandates that neonatologists ensure timely

diagnostic examinations by an ophthalmologist with expertise in ROP.

General Examination Techniques

The Newborn Eye Examination:
Approach and Equipment

Effective physical examination of the newborn eye begins with familiarity with eye anatomy. Armed with a baseline understanding of “normal,” the pediatrician can identify abnormalities or asymmetries in the structure or function of the eyes by following a simple examination framework: *I-ARM* (inspection, acuity, red reflex, and motility) (Simon and Calhoun, 1998). Detailed information on each of these components follows a discussion of general considerations when one is examining the eyes of a young infant.

A thorough eye examination, although necessary, can be stressful and sometimes painful for a newborn or a young infant. ROP examinations in particular, which often necessitate the use of an eyelid speculum to retract the eyelids and scleral indentation to visualize the peripheral retina, have been associated with an increase in pain as assessed by validated pain scores (Premature Infant Pain Profile [PIPP] and CRIES, an acronym for the variables in the scale: Crying, Requires O2 for Sat >95, Increased vital signs, Expression, Sleepless) (Belda et al., 2004). The procedure has also been associated with other adverse effects, including episodes of desaturations, bradycardia, hypertension, and prolonged crying times (Rush et al., 2004). Swaddling, nesting, nonnutritive sucking, and oral administration of sucrose before, during, and after an examination can be very helpful in this regard (Gal et al., 2005; Grabska et al., 2005., Boyle et al., 2006), particularly for premature babies undergoing serial ROP examinations. The most distressing aspects of the eye examination are generally the bright light of the ophthalmoscope and the insertion of the speculum. The use of a topical anesthetic, such as proparacaine hydrochloride 0.5% or tetracaine 0.5% drops, reduces the discomfort but is not always sufficient and should be supplemented with other measures, such as sucrose, pacifiers, and nesting (Marsh et al., 2005; Dempsey et al., 2011). In addition, NICU and office staff should be aware that the repetitive use of topical anesthetics can result in corneal ulceration and melting, so bottles should be properly disposed of

and not confused with other medications, such as topical lubricants or antibiotics. Use of an indirect ophthalmoscope without a speculum produces significantly less pain response than that noted during examination with a speculum or with a contact fundus camera, such as the RetCam (Clarity Medical Systems, Pleasanton, California, United States) (Mehta et al., 2005). Nevertheless, a speculum is often necessary to adequately visualize ocular structures and should always be used if adequate visualization of the fundus is otherwise not possible. Supportive measures can also be used at the time of administration of dilating eye drops. Cohen et al. (2013) analyzed masked videotapes from before, during, and after eye drop administration and found that one-third of infants have a significant pain response to mydriatic eye drops. Finally, particular note should be made of the oculocardiac reflex, a dysrhythmia, typically bradycardia, resulting from direct manipulation of the eye during and immediately after the examination; monitoring by an assistant during and after the examination is therefore important. Nevertheless, in the experience of the authors, it is extremely rare for a properly supported infant to be unable to tolerate a quick fundus examination, the discomfort of any observers notwithstanding. Therefore we recommend that eye examinations not be postponed unilaterally by the neonatology team without their first discussing with the ophthalmologist the risk of ROP in each specific infant.

The infant is often examined best while lying supine. If he or she is in an incubator, the top must be raised to allow the examiner to examine the eyes closely and from different directions. A parent or a nurse may cradle the baby for examination as well. In slightly older infants, visual tracking and motility are best assessed with the infant in an upright position. It usually takes more than one set of hands to examine an infant's eyes. As discussed earlier, assistance with comforting the baby and monitoring vital signs is important. In addition, the head and body of the infant may need to be securely held to allow both a detailed and a safe anatomic examination. Such restraint should be applied carefully but firmly and is best left to the end of the examination, because once the child is upset, it will become difficult to assess certain parts of the ophthalmologic examination, such as visual function, motility, or intraocular pressure. Under some circumstances, it may become necessary for an ophthalmologist to perform an examination with the infant under sedation or general anesthesia.

Examination of the eye requires adequate light and magnification. Even a simple flashlight or penlight and a magnifying glass are helpful and worth using if specialized instrumentation is not available. The ideal light source provides a variable, very bright and focused beam. The portable slit lamp microscope combines such a light source in combination with excellent binocular magnification. The light beam width is controllable, allowing three-dimensional cross sections of the anterior segment structures of the eye, including the conjunctiva, cornea, anterior chamber, iris, and lens. Although the slit lamp is an extremely useful instrument, it is expensive, and practice is needed to develop facility. Again, any simple magnifier and bright light source will prove invaluable for an eye examination in the NICU, emergency department, or primary care provider's office. The direct ophthalmoscope, typically available in all three settings, can serve this purpose and is discussed in the next paragraph. An additional method of identifying disease of the ocular surface is application of fluorescein ophthalmic solution, which will stain areas of denuded corneal and conjunctival epithelium. Once the solution has been applied, a blue light source must be shone on the eye, and the examiner can identify corneal abrasions, which appear as patches of staining; corneal dryness, which appears as punctate staining; and multiple other conditions, such as dendritic herpetic

lesions. Most direct ophthalmoscopes have a blue light source, which may be used in conjunction with a magnifier. Alternatively, a Wood's lamp may be used.

The direct ophthalmoscope is an important instrument for examining a newborn's or an infant's eyes. It provides a light source to evaluate light perception and pupillary reactivity and to be used together with a magnifier for examination of the anterior structures of the eye. Red reflex testing with a direct ophthalmoscope (described in detail later) is a mandatory element of all newborn and well-baby physical examinations. Numerous vision-threatening and even life-threatening ocular diseases are primarily identified by the checking of red reflexes, and this technique is the principal method of detecting disease in the posterior segment of the eye. The direct ophthalmoscope may, of course, be used to directly visualize the optic nerve head and retina, but particular considerations and limitations must be kept in mind. Pupil size must be maximal; typically this means pharmacologic dilation (discussed later). If mydriatics are not used, dimming ambient light and, in older children, having the child fixate in the distance will maximize pupil dilation. The examiner must be very close to the infant (a few centimeters at most). Approaching from a slightly lateral angle and following the "arrows" of branching vessels back to the nerve head will help to identify the optic disc. Most important, the field of view or "spot size" of the direct ophthalmoscope is approximately the size of the optic nerve head, which represents but a tiny fraction of the ocular fundus. Therefore it is not possible to adequately evaluate the retina for ROP or other peripheral retinal disease with a direct ophthalmoscope; instead an indirect ophthalmoscope is needed. This instrument requires both greater skill and a handheld lens to use but provides binocular viewing with depth perception and a much wider field of view. Pharmacologically dilated funduscopic examination with an indirect ophthalmoscope is required for ROP and other retinal diagnostic examinations, such as for retinoblastoma or retinal hemorrhage (RH) in suspected abusive head trauma (AHT).

Pharmacologic dilation with mydriatic eye drops is commonly performed by consulting ophthalmologists, typically on all new patient evaluations and at all ROP examinations. Occasionally, a pediatrician may find it helpful to dilate the pupils to better visualize the red reflex or optic nerve head. Use of drops is better deferred if an ophthalmology consultation will be requested, because dilating the pupils may make it difficult or impossible to accurately assess the pupils, ocular alignment, intraocular pressure, or iris. Dilating eye drops include sympathomimetic drugs (e.g., phenylephrine) and anticholinergic drugs (e.g., tropicamide, cyclopentolate, atropine). Potential side effects of these drugs include elevated blood pressure, increased heart rate, cardiac arrhythmias, feeding intolerance, slowed gastric emptying, urticaria, contact dermatitis, and seizures (Isenberg et al., 1985; Bonthala et al., 2000; Chew et al., 2005). Bradycardic and apneic episodes following administration of these eye drops are pain response reactions and not a direct effect of the drugs. Adverse effects are potentially of greater concern in preterm infants, who are of lower weight and typically require multiple doses to achieve adequate dilation, as do many children with dark irides. Therefore it may be prudent to use reduced concentrations of mydriatics in premature infants, particularly cyclopentolate. In a randomized masked trial, Chew et al. (2005) concluded that cyclopentolate 0.2% with phenylephrine 2.5% is the mydriatic of choice in preterm infants with dark irides, because higher concentrations of cyclopentolate (0.5%, 1.0%) were more likely to result in increased mean blood pressure or feeding intolerance. In all children, systemic absorption of eye drops can be

minimized by compression of the lacrimal sac for 1 to 2 minutes after instillation. It is also recommended to wipe all the overflow drops from the skin as local vasoconstriction and pallor of the periorbital skin is frequently observed in premature neonates in whom the epidermal permeability barrier is still incompetent (Alpay et al., 2010). These authors typically use three drops of Cyclomydril (cyclopentolate hydrochloride 0.2% and phenylephrine hydrochloride 1%) or tropicamide 1% and phenylephrine 2.5% separated by 5 minutes in each eye, 30 to 60 minutes before the examination. Multiple doses are necessary because in premature and newborn babies, adequate pupil dilation is often difficult to obtain because of the immaturity of the dilator muscle of the pupil; the pupils of babies with dark irides, in particular, may be more difficult to dilate because of pigment binding of the mydriatic drugs, and higher concentration or more frequent administration may be required. We recommend avoiding the use of cyclopentolate 1% in children younger than 6 months.

Inspection (the I in I-ARM)

Inspection of anatomy is the primary method of detecting eye disease. The eyes should be closely examined with proper lighting and magnification (as described earlier), and the periocular and ocular structures should be approached in a systematic manner. One option is to begin with the external structures and work inward and posteriorly, looking at each eye carefully and comparing the two eyes with each other. As a guideline, any abnormality or asymmetry noted on examination should be referred to a pediatric ophthalmologist for further management. The urgency with which to seek consultation depends on the specific finding, and guidelines appear throughout this chapter. However, one should err on the side of urgency, because the neonatal period is a critical period in visual development. To adequately inspect the eyes, familiarity with normal anatomy is required. A general overview of these structures follows (Fig. 108.1).

The eyelids protect the eyes. The eyelids contain numerous glands, which produce tears to keep the ocular surface well lubricated. Blinking spreads the tears and actively pumps the tears into the lacrimal drainage system. An inability to adequately close the eyes presents a major problem and can result rapidly in surface drying, corneal epithelial breakdown, and vision- or eye-threatening

complications, such as ulceration, infection, or scarring. Use of an overhead heater should be avoided for infants who have poor eyelid closure (e.g., congenital eyelid abnormalities, neurologic problems), as the ocular surface can rapidly decompensate in such cases; alternative sources of maintaining body temperature should be used, and an ophthalmology consultation should be requested to manage the ocular surface. The nasolacrimal duct provides a means of egress for tears, which pass through the puncta, canaliculi, and lacrimal sac to the duct. The duct is blocked at birth in 5%–10% of newborns, resulting in epiphora and discharge in an otherwise white and quiet eye; 90% of such blockages clear by 1 year of age. Of note, congenital glaucoma can manifest itself with epiphora as well (see [Corneal Clouding](#)).

The conjunctiva is a translucent membrane that overlies the surface of the eye and the inside of the eyelids. The sclera is the white fibrous wall of the eye. It is relatively flexible at birth and gradually toughens over the first few years of life. The cornea is continuous with the sclera, which it meets at the limbus, and is a clear dome-shaped structure in the center of the globe (eye). The cornea provides two-thirds of the refractive power of the eye, is richly supplied with sensory nerves, and must be kept well lubricated to prevent surface breakdown. The cornea is a multilayered structure approximately 0.5 mm thick, kept clear by active pumping out of fluid by its endothelium. Any process that affects the clarity or integrity of the cornea can result in loss of vision.

The iris is a donut-shaped structure posterior to the cornea. The anterior chamber of the eye lies between the cornea and the iris and is best visualized with slit lamp examination (see the earlier discussion). The anterior chamber angle lies at the juncture of the cornea and iris peripherally and contains the aqueous fluid drainage structures of the eye; if these structures are occluded, a rapid rise in intraocular pressure and sight-threatening glaucoma can ensue. Such angle-closure glaucoma is uncommon in children. The iris contains muscle structures to constrict and dilate the pupil, which is a central aperture under involuntary control and changes size with variations in incident light, focusing effort (accommodation), emotions, and medications. The iris is an immature structure at birth. The color tends to be gray or blue and may become darker as the pigmented layer of the iris stroma becomes more fully developed, which typically occurs by about 6 months of age. *Heterochromia* refers to differences in the color of the iris between

• Fig. 108.1 Anatomic structures and common neonatal diseases by anatomic site.

or within eyes and can be seen in congenital Horner syndrome (with mild ptosis and a miotic pupil), as well as syndromic conditions such as Waardenburg syndrome or Hirschsprung disease. Behind the iris lies the crystalline lens, which provides one-third of the eye's refractive power. The lens width and therefore refractive power can be varied by contraction of the ciliary muscle of the eye to provide accommodation or "focusing-in" ability. An opacity in the lens is referred to as a cataract (see [Leukocoria and Abnormal Red Reflex](#)). The uvea is composed of the iris, the ciliary body, and the choroid. Inflammation of the uvea, uveitis, is diagnosable with a slit lamp and dilated fundus examination by directly visualizing white blood cells in the anterior chamber, as well as multiple other signs in the anterior and posterior segments of the eye. The ciliary body produces aqueous humor, which maintains eye pressure and nourishes the anterior segment structures. The choroid is a vascular structure that lies between the sclera and the retina; it supplies the retina and is the most densely packed blood supply in the body.

The retina is a multilayered, complex, highly metabolically active structure that lines the inside surface of the globe and contains photoreceptors that receive light and generate neuronal signals that are ultimately perceived as visual images. The macula is the central, posterior retina, between the superior and inferior temporal retinal vascular arcades, and the fovea is the very central retina containing the highest concentration of photoreceptors and producing central, high-resolution vision. Visual signals are transmitted through the optic nerve, whose cell bodies lie in the most anterior retina and which is composed of approximately 1 million individual nerve fibers. The proximal end of the optic nerve is visible as a normally golden disc approximately 15 degrees nasal and just superior to the fovea. The optic nerves lead to the optic chiasm and continuing visual and pupillary pathways in the brain. The anterior portion of the eye contains aqueous humor, and the posterior segment contains vitreous humor, which is well formed at birth but which undergoes gradual liquefaction (syneresis) with age. The vitreous is attached to the retina throughout the fundus (posterior inner surface of the eye), all the way to the retina's anterior extent or ora serrata, where the retina meets the ciliary body; however, it has particularly strong attachments at the ora serrata (vitreous base), at the optic nerve head, and along the retinal vessels in the most superficial layers of the retina.

Knowledge of normal eye structures and certain growth parameters in the newborn is important because a deviation from the averages can be associated with significant disease. For example, in congenital glaucoma, the corneal diameter is increased, and the axial length (sagittal length) of the eye is a parameter that is carefully followed by the ophthalmologist, with the aid of an ultrasound examination, to determine if the intraocular pressure is adequately controlled. At birth the eyeball is 70% of the adult size (average axial length in a newborn is 17 mm) and reaches 95% of the adult size by age 3 years. The corneal horizontal diameter is usually 9.5 mm at birth, which is 80% of the adult diameter. Corneal diameter can be assessed by simple bedside examination.

Acuity and Visual Development (the A in I-ARM)

The visual system is immature at birth. The fovea is not completely differentiated until 15 to 45 months ([Hendrickson and Yuodelis, 1984](#)), and myelination of the optic nerve is not completed until about 1 year of age ([Magoon and Robb, 1981](#)). The eye continues to develop synapses in the visual cortex during the first 10 years after birth, and although visual acuity reaches normal adult ranges by 2 years of age, this period continues to be important because

any abnormality can lead to amblyopia (see the definition later). Color vision improves greatly during the first 3 months after birth, and most normal 3-month-olds have at least some color vision; color visual processing mechanisms continue to mature throughout the first year of life ([Brown, 1990](#); [Yang et al., 2015](#)).

Because of the immaturity of the system at birth, qualitatively estimating the vision of a newborn is seldom attempted, and other clues to the status of visual function are more commonly used. However, clinical and laboratory techniques can be used to estimate vision in special situations. These include eliciting a nystagmus response with optokinetic targets (striped patterns), Teller cards for preferential forced looking (a test that depends on an infant's preference to look at patterns—grating of black and white stripes—rather than homogeneous fields), visual evoked potentials, and electroretinogram. Each of these techniques uses different stimuli and yields somewhat different results, but they all demonstrate a dramatic improvement in "acuity" during the first year of life. Most commonly, visual function in a newborn is assessed by detection of light aversion, which implies light perception. A bright light is shone into each eye or even through the thin eyelids to elicit closing or squeezing of the lids. Although visual fixation may be intermittently present soon after birth, it is not well developed until after the second month; in contrast, a blink response to light is already present at 26 weeks' postmenstrual age (PMA) ([Robinson and Fielder, 1990](#)), and head turning to a diffuse light starts around 32 weeks' PMA. A blink in response to an approaching object (visual threat response) does not develop until approximately 16 weeks' postnatal age. An infant should fix on and follow a face or object by 2 to 3 months of age. A clever technique that is based on the observation that neonates and infants will attend to the reflection of their own faces in a mirror has been described ([Bowman et al., 2010](#)). Measurement of the "mirror distance" is a simple and reliable technique to estimate visual acuity in infants that can be used as a screening test similar to the traditional "fix and follow" (see later) and is a useful additional tool for detecting impaired visual function at this early age ([Bowman et al., 2010](#)). Generally, the absence of visual responsiveness by a developmental or corrected age of 2 months should be taken seriously and prompt an urgent ophthalmologic evaluation.

Poor vision or blindness should be suspected in any infant with absent or poor pupillary responses, paradoxical pupillary response (initial brisk constriction of the pupil when the lights are turned off) ([Frank et al., 1988](#)), and nystagmus or roving eye movements, although these are not usually present until 2 to 3 months of age. Constant poking or rubbing the eyes can also be a sign of poor vision.

Causes of congenital blindness or poor vision include Leber congenital amaurosis (an early and severe form of retinitis pigmentosa), other retinal dystrophies (achromatopsia and congenital stationary night blindness), congenital cataract, glaucoma, aniridia, albinism, optic nerve abnormalities (hypoplasia and coloboma), chorioretinal colobomas, high refractive errors, and congenital infections. In most babies the cause of poor vision is obvious after complete ophthalmologic examination. Occasionally, further investigation is necessary and may include electrophysiologic testing and neuroimaging. Babies with cerebral (central or cortical) visual impairment (CVI) have normal eye examination findings, including normal pupillary responses and no nystagmus. CVI is used to describe children with visual impairment as a result of neurologic disease, which may be congenital or acquired. Perinatal causes include intrauterine infection, cerebral dysgenesis, asphyxia, hypoglycemia, intracranial hemorrhage, periventricular leukomalacia,

hydrocephalus, trauma, meningitis, and encephalitis. In developed countries, CVI is the single greatest cause of visual impairment in children, and most of these children have an associated neurologic deficit (usually epilepsy or cerebral palsy), which places a major burden on children's special services in these countries.

Amblyopia is defined as a reduction in best corrected vision that cannot be attributed directly to any structural abnormality of the eye or proximal visual pathway. Amblyopia is maldevelopment of the visual centers of the brain as a result of abnormal visual experience early in life. It includes three etiologic categories, which often overlap. Deprivational amblyopia results from obstruction at any point in the visual axis that causes the retina to perceive poor-quality, distorted, or no images. The causes of deprivational amblyopia include congenital or acquired cataract, corneal opacity, ptosis, and vitreous hemorrhage. Strabismic amblyopia results from a child's preferring one eye over the other when the visual axes are misaligned. Refractive amblyopia is a consequence of either a significant inequality of the refractive error in each eye or very high refractive errors in both eyes. Any of these forms of amblyopia can be encountered in the first few months of postnatal life. Because amblyopia is responsible for more cases of unilaterally reduced vision in childhood than all other causes combined, and because it is highly preventable with early detection and treatment, all newborns and infants suspected of having any of these conditions should be referred promptly to an ophthalmologist.

Pupillary Response and the Red Reflex (the *R* in *I-ARM*)

The onset of the pupillary light reflex (constriction in response to light) occurs around 30 to 34 weeks' gestation (Robinson and Fielder, 1990) and is not fully developed until the first month after birth. The pupils should be examined for size, shape, symmetry, reactivity to light, and afferent defects.

As the light passes through the pupils and is reflected through the normal clear media of the anterior and posterior segments of the eye, a characteristic red reflex is produced. The reflex is generated not from the retina, which is transparent, but from the choroidal pigmentation and vasculature. The red reflex test is vital for early detection of vision and potentially life-threatening conditions such as cataract, glaucoma, retinoblastoma, retinal abnormalities, systemic diseases with ocular manifestations, and high refractive errors. Red reflex assessment is an essential component of every neonatal and infant physical examination. The American Academy of Pediatrics currently recommends that all neonates have an examination of the red reflex before discharge from the neonatal nursery. In addition, the test should be performed during all subsequent routine health supervision visits (Donahue, 2016a; Donahue, 2016b).

The red reflex test should be performed in a darkened room, projecting the largest white-light circle light of the ophthalmoscope onto both eyes of the infant—first simultaneously, from approximately 18 inches away, while looking through the aperture of the ophthalmoscope. Once the reflexes have been assessed together to allow comparison, specific abnormalities can be more closely inspected by examination of each eye separately at a nearer distance. Since neonates and infants are frequently asleep and it is difficult to open their eyes and keep them open, the red reflex test may be challenging. A useful technique to encourage a neonate to spontaneously open the eyes is the use of a primitive reflex seen in neurologically healthy children up to 6 months old: the child is supported by a hand on the thorax at approximately a 45-degree angle from

the horizontal with use of the other hand to jiggle the child's bottom (McLaughlin and Levin, 2006).

It is not necessary to pharmacologically dilate the pupils, although the reflexes are easier to assess with larger pupils; indeed, the most common cause of an absent reflex is small pupils. Darkening the room or changing the light beam of the ophthalmoscope will usually overcome this problem. Although traditionally the normal reflex has been described as "red," it can often be yellow, orange, or maroon. The symmetry of the color, clarity, and intensity of the red reflex between the eyes is usually more useful than the qualitative assessment of each red reflex independently, as there may be significant variation in normalcy. A markedly diminished or dim reflex, the presence of a white reflex (leukocoria), dark spots in the reflex, or an asymmetric reflex between the eyes is an indication for immediate referral to an ophthalmologist experienced in the examination of children (Donahue, 2016a). An exception to this rule is a transient opacity in the tear film from mucus or a foreign body that is mobile and completely disappears with blinking or manual opening and closing of the eyelids, after which the red reflex should appear normal. Unequal or high-refractive errors (need for glasses) and strabismus may also produce abnormal or asymmetric red reflexes. An additional observation is the position of the light reflex on the corneal surface. Asymmetric positioning of this reflex can indicate misalignment of the eyes (strabismus; see later).

In addition, the shape and regularity of each pupillary aperture should be assessed to look for colobomas (Fig. 108.2A) and other congenital abnormalities (see Common Diagnostic Problems). Asymmetry of pupil size (anisocoria) can be a sign of Horner syndrome, trauma, or a congenital third nerve palsy. The tunica vasculosa lentis is a plexus of vessels that crosses the pupil, visible in preterm babies up to 34 weeks' PMA. The extent of this anterior lens capsule vascularity can be used to estimate gestational age in babies between 27 and 34 weeks' gestation (Hittner et al., 1977; Krishnamohan et al., 1982; Zimmer et al., 1983). A failure of these vessels to regress can occasionally be seen as a persistent pupillary membrane, which appears as a regular arrangement of vessels looping into the pupillary axis in front of or behind the lens.

Motility and Alignment (the *M* in *I-ARM*)

Although the extraocular muscles are formed by 12 weeks' gestation and fetal eye movements can be detected as early as 16 weeks' gestation, the supranuclear eye movement system is not fully developed until after birth in full-term neonates. The eyes of a neonate commonly appear misaligned. It is not unusual to see the eyes shift from straight (orthotropia) to crossed inward (esotropia) to outward (exotropia). Transient deviations (neonatal ocular misalignments) occur very commonly in the first month of life in visually normal infants. At this age it is not possible to distinguish those infants who will progress to develop pathologic strabismus from those who will develop normal binocular vision (Horwood, 2003a). Exotropia is commonly observed in newborn nurseries and has been reported to occur in up to 33% of infants (Nixon et al., 1985); however, most exodeviations will usually resolve with development of the fixation reflex and are rarely observed beyond 6 months of age (Sondhi et al., 1988). In contrast, transient esodeviations in patients who do not go on to develop infantile esotropia do not usually persist beyond 10 weeks of age (Sondhi et al., 1988; Horwood, 2003b). Most full-term infants establish normal ocular alignment within the first 8 weeks of life. In some

• **Fig. 108.2** Wide spectrum in presentation of colobomas of the eye. (A) Iris coloboma, notice the difference in red reflex at the lens equator. (B) Microphthalmos with coloboma (the left eye is smaller because of a uveal coloboma). (C) Noncontiguous optic nerve and chorioretinal coloboma. (D–F) Optic nerve colobomas. (G) Small chorioretinal coloboma inferior to the optic disc. (H) Large chorioretinal coloboma involving most of the posterior pole. (I) Large chorioretinal coloboma involving the macula and optic disc.

babies the epicanthal folds of the eyelids hide the medial aspect of the sclera, creating the appearance of strabismus; however, in these cases the visual axes are not misaligned. This common condition is referred to as *pseudostrabismus* (Fig. 108.3B) and can be confirmed by the directing of a bright light to both eyes simultaneously and observing that the reflection of the light on the corneas appears symmetric between the eyes with respect to the center of

the pupil; the reflexes will appear asymmetric between the eyes if a true misalignment exists (see Fig. 108.3A).

Most cases of strabismus in infants are not paralytic in origin, but congenital third, fourth, and sixth nerve palsies can occur, as well as early acquired cranial neuropathies due to trauma, infection, and other central nervous system abnormalities. When there is doubt, any apparent misalignment after 3 to 4 months of age

• **Fig. 108.3** (A) Inward misalignment of the eyes in a premature child with infantile esotropia. (B) Pseudoesotropia or pseudostrabismus (a wide nasal bridge and prominent epicanthal folds give the appearance of esotropia; note the position of the corneal light reflex centered in the pupil of both eyes).

should be considered pathologic and referred for evaluation (Donahue, 2016a). This is especially important as, in some cases, strabismus can also be the first sign of serious ocular or systemic disorders. Premature and low birth weight infants are at increased risk of developing strabismus and other amblyogenic conditions throughout their childhood. Perinatal stroke is also associated with a high incidence of strabismus, early head turn, visual field cuts, and other vision abnormalities. Such high-risk infants as well as those with a strong family history of strabismus or amblyopia should be referred for evaluation.

It is recommended that all newborns have an ocular motility assessment (Donahue, 2016b). In addition, since vision in young nonverbal children is mostly assessed by evaluation of the child's ability to fix on and follow an object, this test provides information on the status of the visual and extraocular muscle systems. A standard assessment strategy is to determine whether each eye can independently fixate on the object, maintain fixation on it for a short period, and then follow it as it is moved in various directions. Neonates and young infants particularly fix and follow the human face or its likeness. This assessment should be performed binocularly and then monocularly in an awake and alert child. In neonates the following may be a jerky saccadic pursuit movement, which represents a series of hypometric saccades to localize the target. If following cannot be demonstrated, it should be verified that the motor system is intact. Range of motion and the ability to generate a saccade may be assessed by inducement of vestibular nystagmus by rotation of the child. If poor fixation and following are noted after 3 months of age, a significant ocular or neurologic abnormality is suspected and should be referred for evaluation (Donahue, 2016b).

Common Diagnostic Problems

Leukocoria and Abnormal Red Reflex

The term *leukocoria* means “white pupil.” It is often used more broadly to encompass a spectrum of opacities and abnormalities. On inspection, the pediatrician may grossly visualize a white lesion in the pupillary space or identify an abnormal red reflex. A white or abnormal reflex may also be identified in recreational photographs taken by family members (Cha et al., 1993; Russell, 2011; Abdolvahabi et al., 2013). The differential diagnosis for leukocoria includes vision- and life-threatening conditions, and leukocoria in an infant or older child requires urgent ophthalmologic evaluation. These conditions include cataract, retinoblastoma, chorioretinal or optic nerve head coloboma, retinal detachment, vitreous hemorrhage, ROP, persistent fetal vasculature, Coats disease, familial exudative vitreoretinopathy, toxocariasis, and uveitis. The distribution differs widely with the population studied. In one series, 60% of 71 children who presented to a tertiary referral center with leukocoria had cataract, 28% had retinoblastoma, and 12% had other retinal abnormalities (Haider et al., 2008).

Cataract

A cataract is any opacification of the normally clear crystalline lens of the eye. Although congenital cataract is much less common than age-related cataract, it is still responsible for approximately 10% of childhood blindness worldwide (Gilbert et al., 1993). Prevention of visual impairment caused by congenital cataract is an important component of the World Health Organization's international program for the elimination of avoidable blindness by 2020 (Thylefors, 1998). Congenital cataracts may be isolated, seen in association with another ocular developmental abnormality, or associated with systemic diseases. The incidence of congenital cataract is approximately 2 in 10,000 live births. Some subtypes of congenital cataracts are small and nonprogressive; dense central opacities larger than 3 mm are considered visually significant. Successful treatment of congenital cataracts may be extremely difficult, and intervention must occur very early in life; therefore early diagnosis is essential. Useful vision can be restored if the surgery is completed within the first 6 weeks after birth. Beyond this time, visual restoration becomes progressively more difficult because of irreversible deprivation amblyopia (Lundvall and Kugelberg, 2002; Birch et al., 2009). The appearance of nystagmus before surgery is an ominous sign of poor visual outcome and adds further urgency for surgical intervention (Lambert et al., 2006). Therefore it is essential that all newborns and young infants have screening eye examinations by a pediatrician, because visual prognosis is directly tied to timely ophthalmologic referral. Cataracts can develop or progress with time, so examination for an abnormal red reflex should be repeated at each well-child visit even if prior examination findings appeared normal.

After surgery, intensive visual rehabilitation strategies must be implemented. If the infant is left aphakic (without a lens), optical correction is achieved with special contact lenses or glasses. Adherence to use of contact lenses, glasses, and, in the case of monocular cataracts, aggressive amblyopia treatment by penalizing (patching) of the sound eye is critical and directly affects the child's ultimate visual outcome. Aphakic glaucoma is one of the most common sight-threatening complications of cataract surgery in infants. It can present soon after surgery or many years later, and it can be very difficult to treat, often requiring multiple surgical procedures.

The pathophysiology of aphakic glaucoma is not well understood, but important risk factors include early age at surgery and smaller corneal diameter (Swamy et al., 2007; Freedman et al., 2015).

Most patients with isolated nonsyndromic cataract have no identifiable cause. Although teratogenic agents (e.g., rubella) may account for a proportion of cases, such insults normally give rise to other systemic malformations in addition to cataract. Genetic mutation is likely to be the most common cause, particularly for bilateral cataract, but the proportion of cases with a genetic basis is still unclear (Reddy et al., 2004; Pichi et al., 2016). Genetic inheritance is most commonly autosomal dominant and rarely autosomal or X-linked recessive (Reddy et al., 2004; Hejtmančík and Smaoui, 2003). Multiple genes are involved in lens development, and numerous genetic loci have been identified (Hejtmančík and Smaoui, 2003; Reddy et al., 2004; Pichi et al., 2016). Marked variability can be present even within the same pedigree, and children with a family history of infantile or juvenile cataracts should be examined early by a pediatric ophthalmologist. The same is true of children with one of the numerous systemic conditions associated with cataracts: intrauterine infections (rubella, varicella); metabolic and endocrine disorders (galactosemia, neonatal hypoglycemia, diabetes mellitus, and hypoparathyroidism); fetal alcohol syndrome; chromosomal disorders (trisomy 21, Turner syndrome, trisomies 13 and 15); dermatologic diseases (congenital ichthyosis, ectodermal dysplasia); skeletal and connective tissue disorders (Smith–Lemli–Opitz, Marfan, Conradi, and Weill–Marchesani syndromes); renal disorders (Lowe, Alport, and Hallermann–Streiff–François syndromes); neurofibromatosis; and myotonic dystrophy. A selective diagnostic evaluation may be pursued in infants with cataract, particularly bilateral cataracts, and may include TORCH titers (including syphilis); urine tests for reducing substance (galactosemia); plasma urea, electrolyte, and urinary amino acid levels (Lowe syndrome); complete blood count and ferritin, blood glucose, calcium, and phosphate levels; quantitative amino acid levels and red blood cell enzyme levels (galactokinase, galactose 1-phosphate uridylyltransferase); genetic consultation; chromosome analysis and next-generation sequencing (focused on the 115 cataract-causing genes known to date); and ocular examination of parents and siblings. Infants with isolated unilateral cataracts often do not have a family history and rarely have associated systemic disorders (Reddy et al., 2004).

Retinoblastoma

Retinoblastoma is the most common ocular malignancy of childhood and accounts for 3% of all childhood cancers. The average age-adjusted incidence rate of retinoblastoma in the United States and Europe is 2 to 5 per million children or 1 in 14,000 to 18,000 live births (Parkin et al., 1988) but is higher in India and Africa (resulting in approximately 9000 new cases per year, of which fewer than 300 are in the United States). Seventy-five percent of patients have unilateral retinoblastoma, and 25% have bilateral retinoblastoma. The successful management of retinoblastoma depends on the ability to detect the disease while it is still intraocular; disease stage correlates with delay in diagnosis. Untreated retinoblastoma is almost uniformly fatal, and the long-term survival rate for disease diagnosed after it has spread outside the eye is less than 50%. In contrast, 5-year survival rates are greater than 90% when timely recognition and referral to centers specializing in retinoblastoma treatment occur (<http://www.1rbw.org>).

Two-thirds of patients receive a diagnosis before 2 years of age, and 95% receive a diagnosis before the age of 5 years (Parkin et al.,

1988). The earliest age at diagnosis reported is 21 weeks' gestation by prenatal ultrasound examination (Maat-Kievit et al., 1993). Abramson et al. (2003) reviewed 1831 consecutive cases of retinoblastoma. The most common presenting sign was leukocoria (54%), followed by strabismus (19%), poor vision (4%), family history with request for early examination (5%), and red eye (5%). The presenting sign was identified first by a family member or friend in 80% of cases, a pediatrician in 8% of cases, and an ophthalmologist in 10% of cases. Among patients presenting with leukocoria, the sign was first identified by a family member in 90% of cases. These findings stress the importance of routine red reflex testing for all children seen by pediatricians, beginning with newborns. Any child found to have leukocoria should be referred to an ophthalmologist for urgent evaluation.

The diagnosis of retinoblastoma can often be made by direct visualization. Imaging studies may provide useful information, including ocular ultrasonography to identify mass lesions and calcifications; magnetic resonance imaging (MRI) to image the globes and identify orbital and central nervous system involvement; and computed tomography (CT) scans to identify calcification, although MRI is now favored over CT for its ability to image soft tissues and to avoid ionizing radiation (Balmer et al., 2006). Treatment modalities include enucleation; systemic chemotherapy; intra-arterial chemotherapy, in which drug is delivered locally via catheterization of the ophthalmic artery; direct intravitreal chemotherapy injection; and focal destructive therapies such as retinal laser photocoagulation or cryotherapy. Radiation therapy, including brachytherapy, stereotactic conformal radiotherapy, and accelerated proton beam irradiation, is also used (Balmer et al., 2006; Shields et al., 2013), but external beam radiotherapy is now rarely indicated.

The retinoblastoma gene, *RBI*, located on chromosomal region 13q14, was the first tumor suppressor gene to be described. Five percent of patients with bilateral disease carry a large deletion involving the 13q14 locus. In those cases, retinoblastoma is part of a more complex syndrome characterized by facial dysmorphic features (thick anteverted earlobes, high and broad forehead, prominent philtrum, and short nose), skeletal abnormalities, mental retardation, and motor impairment. Children with germline mutations are at increased risk of developing nonocular tumors. Genetic counseling of affected parents is critical to estimate the risk of transmitting the disease to their children. Regardless of the clinical presentation, it is recommended that all patients undergo genetic testing.

Persistent Hyperplastic Primary Vitreous (Persistent Fetal Vasculature)

During embryogenesis and fetal development, the “primary vitreous” contains the hyaloid vasculature system, which fills the posterior segment of the eye and comes forward to surround the lens. This system normally disappears, and a spectrum of abnormalities can be seen when these structures fail to regress, ranging from persistent pupillary strands to a vascular stalk remnant to a retrolenticular membrane and retinal disorganization or detachment. Involved eyes are typically microphthalmic, and an abnormal red reflex or leukocoria may be identifiable. Depending on the extent, surgical intervention may help to avoid recurrent hemorrhage, glaucoma, and phthisis bulbi (atrophy and degeneration of a blind eye, which can become painful), and in some cases useful vision can be achieved (Dass and Trese, 1999). Persistent hyperplastic primary vitreous (PHPV) is the most common retinoblastoma-simulating lesion,

followed by Coats disease and presumed ocular toxocariasis (Shields et al., 1991).

Coloboma

An ocular coloboma is a congenital anatomic defect or cleft that results from failure of the optic fissure to close during embryogenesis (Gregory-Evans et al., 2004). The result is essentially an area of missing tissue in the eye, most commonly in the inferonasal quadrant. Depending on the population studied, its incidence ranges from 0.5 to 7.5 per 10,000 births and accounts for 3%–11% of blind children worldwide (Gregory-Evans et al., 2004). Involved structures can include the iris, ciliary body, retina, choroid, and optic nerve (see Fig. 108.2). An iris coloboma appears as an irregular “keyhole,” or “cat’s-eye” pupil (see Fig. 108.2A). A chorioretinal or optic nerve head coloboma, depending on the size, will appear as an abnormal red reflex or leukocoria. The affected eye may be microphthalmic (see Fig. 108.2B). The visual prognosis depends on whether the central macula is involved, and children may have good central vision despite upper visual field defects if the macula is spared. Long term, there is a variable risk of complicating retinal detachment or choroidal neovascularization associated with retinal and optic nerve colobomas (Gregory-Evans et al., 2004). An ocular coloboma can be isolated or syndromic. There are numerous ocular abnormalities and systemic findings associated with coloboma, and more than 200 syndromes have been described. Examples include the CHARGE association, 22q11 deletion, and Treacher Collins, Walker–Warburg, and Aicardi syndromes. The systemic diagnostic testing in patients with apparently isolated bilateral or unilateral uveal coloboma should include a kidney ultrasound examination, audiometry, and spine radiographs. In addition, an echocardiogram and neuroimaging could be considered (Nakamura et al., 2011; Huynh et al., 2013).

Corneal Clouding

Slightly cloudy corneas can be seen in otherwise normal healthy newborns and normally clear within 1 to 2 days. Clouding is commonly seen in small for gestational age and premature infants, and it is proportional to the degree of prematurity. At 26 weeks’ gestation the degree of cloudiness is significant enough to prevent the evaluation of the iris details underneath, and along with an immature hyaloid vascular system, it prevents a detailed view of the posterior segment structures (retina and optic nerve). This is an important consideration when the ophthalmologist is asked to evaluate premature infants soon after birth for intraocular spread of systemic infections (endophthalmitis) or structural anomalies in suspected genetic diseases, etc. Slowly, as the child matures, the cornea establishes transparency and most of the time is sufficiently clear to allow retinal examinations for ROP by 30 to 32 weeks’ postconceptional age.

Persistent opacification of the cornea in a newborn may be the result of congenital glaucoma, corneal dystrophies, developmental abnormalities of the cornea and/or other anterior segment structures (Fig. 108.4), infection, iatrogenic trauma, or metabolic disorders. Close inspection with magnification will identify opacification in a focal, regional, or diffuse pattern, depending on the cause. The cornea is normally clear all the way to its border with the sclera (the limbus), with iris details easily visible underneath; these details will be obscured when the cornea is opacified. A large or central opacity will also result in an abnormal red reflex. When identified, congenital corneal opacification requires urgent ophthalmologic

• Fig. 108.4 Cloudy cornea secondary to anterior segment dysgenesis.

evaluation to rule out congenital glaucoma, infection—which could become eye or life threatening—or an opacification that is amenable to surgical correction during the early critical period in visual development.

Glaucoma is an optic neuropathy usually associated with raised intraocular pressure. In contrast with adult- or juvenile-onset glaucoma, which may be successfully managed medically, congenital glaucoma is a surgical disease that requires prompt intervention, frequently in the neonatal period. Vision loss from glaucoma is typically irreversible. Key signs to identify include corneal clouding (not always), corneal and eye enlargement (buphthalmos), tearing, blepharospasm (blinking), Haab striae (tears in the Descemet membrane, seen as lines in the red reflex), and photophobia. It is worth highlighting that tearing is a sign of glaucoma, not just of a blocked tear duct. Finally, congenital glaucoma has multiple systemic associations, such as Sturge–Weber syndrome, neurofibromatosis, Lowe syndrome, congenital rubella, and Rubenstein–Taybi disease.

Sclerocornea is characterized by cornea that is opacified and white like the sclera, with which it is developmentally continuous. Typically, these opaque areas are located at an indistinct corneoscleral limbus (border), can extend centrally, and contain superficial vascularization. It can occur in isolation or can be associated with cataract, microphthalmos, and/or infantile glaucoma (Nischal, 2007). In contrast to sclerocornea, *Peters anomaly* classically has a central corneal opacity with clear cornea peripherally, absence of posterior corneal stroma, and variable attachments between the posterior corneal surface and the iris and/or lens (Yang et al., 2009). The encompassing term *anterior segment dysgenesis* is sometimes preferred to describe many of these developmental anomalies of the cornea and anterior segment that result in congenital corneal opacities and congenital glaucoma as there is significant overlap and variability in their presentation (see Fig. 108.4).

Infectious keratitis can be herpetic with characteristic epithelial dendritic ulcers and corneal stromal inflammation. *Bacterial keratitis* is less common in countries that practice routine administration of conjunctivitis prophylaxis at birth. However, a bacterial corneal ulcer can begin as a corneal abrasion (see the later discussion) and then quickly enlarge, resulting in corneal thinning or perforation, endophthalmitis, and even bacterial sepsis. In the authors’

TABLE 108.1 Diagnostic Features and Management of Neonatal Conjunctivitis

| Etiologic Agent | Onset | Clinical Characteristics | Diagnosis | Treatment |
|---|-----------|---|--|---|
| Chemical | 24 h | Noninfectious Lid edema, watery discharge | History of exposure, self-limited in <48 h | None |
| Gonococcal (see Fig. 108.5) | 3–4 days | Bilateral, hyperacute purulent conjunctivitis, marked lid edema, copious discharge Can perforate cornea | Cell culture and Gram stain Gram-negative intracellular diplococci | Ceftriaxone 25–50 mg/kg daily intravenously Topical irrigation Topical antibiotics useful only if corneal ulcer present |
| <i>Chlamydia trachomatis</i> (most common) | 5–7 days | Mild mucopurulent nonfollicular conjunctivitis, lid edema, pseudomembrane formation Pneumonitis after 3–12 weeks | Cell culture, Giemsa stain, direct immunofluorescent assay, enzyme-linked immunoassay, PCR Basophilic intracytoplasmic inclusions in epithelial cells | Orally administered erythromycin, 12.5 mg/kg every 6 h for 2 weeks or azithromycin suspension, 20 mg/kg orally daily for 3 days |
| <i>Staphylococcus</i> , <i>Streptococcus</i> , and other bacteria | 5–14 days | Nosocomial, mucoid discharge, conjunctival hyperemia, and chemosis | Cell cultures, Gram stain | Broad-spectrum topical antibiotic (e.g., polymyxin B–trimethoprim, one drop every 4 h for 7 days) |
| Herpes simplex virus | 6–14 days | Unilateral or bilateral conjunctivitis (nonfollicular), serous discharge, associated lid vesicles, and, occasionally, corneal epithelial dendritic defects that stain with fluorescein with or without systemic involvement | Cell cultures, direct fluorescent antibody staining, enzyme immunoassay detection, PCR Multinucleated giant cells with intracytoplasmic inclusions | Acyclovir, 60 mg/kg per day in three divided doses for 2 weeks (3 weeks if CNS or disseminated disease) plus topical drops (1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine) |

CNS, Central nervous system; PCR, polymerase chain reaction.

experience, this chain of events can also occur in reverse, with bacteremia seeding the eyes and ultimately manifesting itself as a keratitis. The findings include a white corneal stromal infiltrate with an overlying corneal epithelial defect that stains with fluorescein. Aggressive topical and sometimes systemic antibiotics are required, and any infant with a red eye and corneal opacity or abnormality should be referred for immediate ophthalmologic evaluation.

Iatrogenic trauma may result in corneal injury and may be the result of amniocentesis or forceps delivery. Injuries from the latter are characterized by linear breaks in the Descemet membrane, which are more likely to be vertical or diagonal than the horizontal breaks seen with glaucoma, and may be accompanied by other signs of trauma.

Corneal dystrophies, such as congenital hereditary endothelial dystrophy and posterior polymorphous dystrophy, may also result in cloudy corneas. The former always manifests itself at birth, whereas the latter may or may not be present at birth (Nischal, 2007). Metabolic disorders, such as some mucopolysaccharidoses, may cause progressive clouding but often do so later in life and rarely during the neonatal period.

Red Eye/Eye Discharge

The most common and important causes of a red eye in neonates include infectious conjunctivitis, subconjunctival hemorrhage, foreign bodies, and vascular malformations.

The incidence of neonatal conjunctivitis (ophthalmia neonatorum) has decreased dramatically since the introduction of prophylaxis in 1881. Despite this, ophthalmia neonatorum still blinds thousands of babies annually worldwide (Isenberg et al.,

1996). The etiologic cause of conjunctivitis in the newborn can be chemical, bacterial, or viral (Table 108.1). Although infections are usually transmitted to the infant by direct contact during passage through the birth canal, organisms can ascend to the uterus, so even infants born via cesarean delivery can be infected, particularly in the setting of prolonged rupture of membranes but even with intact membranes (Gallardo et al., 2005). Prophylactic agents include 1% silver nitrate, 0.5% erythromycin ointment, 1% tetracycline ointment, and 2.5% povidone–iodine (Isenberg et al., 1995, 1996). No prophylactic agent completely eliminates the risk of developing an infection, and a high index of suspicion should be maintained, in particular in those patients with risk factors (maternal infection, lack of prenatal care, or premature rupture of membranes). Gentamicin ointment should be avoided, as it is associated with periocular ulcerative dermatitis when used on the newborn eye (Binenbaum et al., 2010).

Despite common teaching, the timing of the onset of conjunctivitis is not a reliable diagnostic clue, because significant overlap exists among the different etiologic agents. For this reason, conjunctival cultures (in Thayer–Martin agar, blood agar, and chocolate agar) and conjunctival scraping for Gram and Giemsa staining are mandatory and should be performed without delay. It is not necessary to wait for an ophthalmology consultation to initiate laboratory investigation and treatment, because delays in treatment of gonococcal conjunctivitis can have devastating consequences. *Neisseria gonorrhoeae* can penetrate an intact corneal epithelium, rapidly leading to perforation of the globe within hours if treatment is not initiated; therefore all forms of conjunctivitis must be considered bacterial until proven otherwise. Appropriate treatment should be instituted once the results of cultures are known but should never be delayed (Fig. 108.5).

• **Fig. 108.5** A 6-day-old newborn with gonococcal conjunctivitis. Note the marked lid edema and copious purulent eye discharge.

The infant with mucopurulent discharge must be distinguished from the infant who exhibits only excessive tearing and a relatively white eye. The latter is most likely to have nasolacrimal duct obstruction, although the possibility of congenital glaucoma must always be ruled out. Congenital obstruction of the nasolacrimal duct is present in about 5% of infants (Paul and Shepherd, 1994) but usually resolves spontaneously by 12 months of age. Usually a thin mucosal membrane at the distal end of the nasolacrimal duct is the cause. Symptoms become manifest by 1 month of age in 80% of cases, with tearing or sticky mucoid discharge. As a consequence of chronic obstruction, secondary infection in the lacrimal sac may occur, a condition known as *dacryocystitis*. Pressure on the lacrimal sac causes a reflux of mucopurulent material from the punctum. This tends to be a low-grade chronic infection although occasionally it can progress to blepharoconjunctivitis and cellulitis. In contrast, acute dacryocystitis, more commonly seen with congenital dacryocystoceles, is a more severe infection that requires prompt intravenous antibiotics (see later). Simple nasolacrimal duct obstruction (NLDO) usually resolves spontaneously within the first year of life; only conservative management is indicated in most cases. This consists of digital massage downward from the lacrimal sac over the nasolacrimal duct on the side of the nose. The massage empties the sac, reducing the opportunity for bacterial growth. Topical broad-spectrum antibiotic drops or ointment, such as bacitracin zinc and polymyxin B sulfate ophthalmic ointment or drops, can be used if there is conjunctival injection and discharge. Referral to an ophthalmologist should be considered if the condition has not resolved toward the end of the first year, because probing and/or intubation of the lacrimal sac is likely necessary to relieve the obstruction (Katowitz and Welsh, 1987), although the optimal timing of surgery remains controversial. A more recent study reported that there was no age-related decline in the success rate of surgical treatment for congenital NLDO in children treated up to 36 months of age (Pediatric Eye Disease Investigator Group et al., 2008).

Preseptal and orbital cellulitis can also manifest with conjunctival injection, chemosis, and discharge. In addition, orbital cellulitis may cause altered ocular motility and pupillary reflexes and proptosis. Both conditions are typically unilateral and can rarely occur in the first month of life, sometimes secondary to acute dacryocystitis from an infected dacryocystocele (see *Ptosis and Other Eyelid and Lacrimal Abnormalities*).

Subconjunctival hemorrhage is seen as a bright red discoloration under the conjunctiva, obscuring the white scleral background, and is common in the perinatal period. In most cases it is caused by elevated venous pressure in the head and neck produced by compression during uterine contractions. Later in life, subconjunctival

hemorrhage may be a feature of child abuse, although it can also occur spontaneously. Subconjunctival hemorrhage in isolation is completely innocuous and usually resolves in 10 to 14 days.

Motility Abnormalities and Nystagmus

Various eye motility and alignment abnormalities can be present in the first month of life. The most common form of strabismus in early infancy is infantile or essential esotropia (see Fig. 108.3A). This form of convergent strabismus is rarely actually congenital, so this term has been abandoned. It is usually present by age 3 to 4 months and is characterized by a large-angle deviation. These children tend to cross-fixate (use the left eye to view the right visual field and vice versa), simulating an abduction deficit, because it is hard to get the child to follow an object to the ipsilateral field. This can easily be mistaken for bilateral sixth nerve palsy. However, sixth nerve palsies in the neonatal period are extremely rare, and an abduction movement can sometimes be elicited by the patching of one of the child's eyes to force the other eye to abduct in search of an object or by use of the doll's-eye (the eyes lag behind the turning of the head from side to side) or optokinetic nystagmus maneuvers. Infantile esotropia is a condition that is not likely to resolve spontaneously without surgical correction. Because of a high associated risk of amblyopia, prompt referral of these patients to a pediatric ophthalmologist within the first few months of life is appropriate. Even if the child's age or systemic condition is not appropriate for surgical correction, patching and other treatments should be initiated as early as possible. Ideally, surgical correction is accomplished early, by 6 to 12 months of age.

Congenital motor nystagmus (infantile nystagmus syndrome) is an involuntary, bilateral, conjugate oscillation of the eyes that develops within the first 6 months of life. Despite the name, the eye movement abnormalities are rarely noticed at birth. Disorders of the anterior visual pathways resulting in blindness or severe visual deprivation very early in life can also result in nystagmus (sensory deprivation nystagmus), which can be manifest as large-amplitude "wandering" eye movements or with a smaller-amplitude, faster movement that resembles the congenital motor form. Nystagmus caused by a visual deficit does not develop until about 3 months of age. Any form of bilateral (and sometimes unilateral) visual deprivation, including cataracts, corneal abnormalities, glaucoma, optic nerve problems, and chorioretinal colobomas, can manifest themselves with nystagmus, and a prompt ophthalmic evaluation is needed to rule out these conditions, which are treatable in some cases. Other conditions such as albinism, achromatopsia (congenital absence of the retinal cones), and aniridia can also result in nystagmus, which is often very similar to motor nystagmus. Since the ocular findings in these conditions are more subtle and easily missed, an electroretinogram is usually recommended before the diagnosis is confirmed. Because of the overlap with identifiable causes, motor nystagmus should always be considered a diagnosis of exclusion, as other ocular and neurologic disorders can manifest with the same clinical characteristics. Certain specific forms of nystagmus are commonly associated with neurologic dysfunction; these include upbeat nystagmus, see-saw nystagmus, and even monocular nystagmus. However, these forms have all been associated with sensory loss, and an ophthalmologic examination is necessary even when neuroimaging studies rule out intracranial disease.

Other transient disorders of the ocular motor system include flutter-like, high-frequency, small-amplitude movements that in newborns may be self-limiting and resolve spontaneously within the first few weeks of life. This saccadic oscillation should not be

confused with nystagmus. Some infants can also exhibit transient downward deviation of the eyes (Hoyt et al., 1980). This disorder can be distinguished from the more serious sun-setting sign, associated with hydrocephalus, by demonstration of intact upgaze movements using vestibular–ocular responses. Neuroimaging fails to demonstrate any underlying neurologic disorder, and the deviation tends to reduce gradually over the following months. A true upgaze palsy and convergent strabismus can be seen in premature infants who sustained intraventricular hemorrhage (Tamura and Hoyt, 1987). Paroxysmal tonic upgaze of childhood is a rare and distinctive syndrome characterized by episodes of sustained conjugate upward deviation of the eyes. Symptoms normally appear in babies younger than 1 year and are characterized by an upward stare with the eyes rolled back, while the chin is held low (possibly to compensate for the abnormal eye position). The horizontal eye movements are normal, as are the rest of the neurologic examination and imaging findings. The condition tends to improve with time (Ouvrier and Billson, 2005).

Ptosis and Other Eyelid and Lacrimal Abnormalities

External inspection of the eyes and eyelids should be performed in every newborn. The eyelids are fused usually until 25 weeks' gestation, but they may rarely remain fused until 30 weeks' gestation. Eyelid colobomas are rare congenital full-thickness defects of missing eyelid, usually involving the upper eyelid border. Eyelid colobomas may be associated with Goldenhar syndrome. The consequent lack of ocular surface coverage places the infant at high risk of corneal abrasion, ulcer, scarring, and vision loss. Such infants require urgent ophthalmology consultation and should not be placed under overhead heaters without adequate ocular protection.

Most cases of congenital ptosis are caused by an isolated developmental anomaly of the levator palpebrae muscle. Other causes include congenital third nerve palsy, Horner syndrome, blepharophimosis syndrome, and Marcus Gunn jaw-winking ptosis, which is a synkinesis between the levator palpebrae and the muscles of mastication. This type of ptosis is characterized by elevation of the lid associated with sucking or chewing.

Because form deprivation amblyopia can occur as a result of complete obstruction of the visual axis, this condition must be managed aggressively by an ophthalmologist familiar with the treatment of eyelid disorders and amblyopia. Even though this type of amblyopia is the most severe and concerning to the neonatologist, it is important to remember that even without complete obstruction of the pupil, amblyopia can occur secondary to the blur induced by astigmatism produced by the ptotic eyelid on the cornea. If vision is not threatened, surgery may be deferred until 4 or 5 years of age, although close follow-up to detect amblyopia is necessary, and many surgeons have argued the benefits of earlier surgery (Katowitz, 2002).

A number of eyelid tumors can be present at birth or shortly thereafter. Capillary hemangiomas are usually not present at birth and appear in the first couple of weeks of life. The lesions can have a superficial component, which is red and sometimes dimpled, resembling a strawberry, and a deeper component, which appears as a deep diffuse purplish mass. The hemangioma grows during the first 6 to 8 months of life and then stabilizes, regresses, and involutes over several years. These lesions are amblyogenic because they can cause mechanical ptosis, obstruct the visual axis, or cause significant astigmatism. Systemic nonselective beta-blockers (e.g., propranolol) have become first-line treatment, showing remarkable

• **Fig. 108.6** (A) Dacryocystocele in a newborn. (B) Manual decompression of mucopurulent material. (Photo courtesy of Robert Kersten, University California San Francisco Department of Ophthalmology, Ocular Plastics and Reconstructive Surgery San Francisco, California.)

effectiveness in causing regression of these tumors (Léauté-Labrèze et al., 2008, 2015). Topically administered timolol can be effective for superficial lesions as well (Chambers et al., 2012). Other treatment options include topical, intralesional, or systemic steroids; interferon alfa; vincristine; and surgical resection.

Capillary hemangiomas should be distinguished from other capillary vascular malformations (such as port wine stains) that are present at birth and do not exhibit regression. These are sharply circumscribed lesions that are usually unilateral. In these patients, Sturge–Weber syndrome should be suspected. When the skin lesion involves the eyelid, an ophthalmologic consultation should be requested to rule out glaucoma (occurring in about 50% of patients) and vascular abnormalities of the choroid.

A dacryocystocele is formed when a proximal and a distal obstruction coexist in the lacrimal sac and the lacrimal sac becomes distended. Clinically it is manifested as a bluish, nontender mass just inferior and nasal to the medial canthus (Fig. 108.6). The bulging of the mucosa at the lower end of the nasolacrimal duct into the nasal cavity can significantly compromise the airway and should be ruled out by inspection of the nasal passage (Paysse et al., 2000). A secondary infection of the distended sac, or dacryocystitis (Fig. 108.7), is not uncommon and can have potentially serious consequences in a neonate, including meningitis and

• **Fig. 108.7** (A) Bilateral dacryocystoceles. (B) Infected dacryocystocele with erythema in medial canthal area and a firm tender mass. (C, D) Dacryocystocele with progression to preseptal cellulitis. (E, F) Dacryocystitis with localized abscess before and after nasolacrimal duct probing with endonasal cyst marsupialization.

septicemia. Intravenous antibiotics should be administered followed by decompression of the sac after 24 to 48 hours if the dacryocystitis shows no abatement. A dacryocystocele should be distinguished from a frontal encephalocele and can occasionally be confused with a hemangioma or a dermoid cyst.

Ocular Trauma in the Neonatal Period

Newborns may experience injuries to the eye as a result of birth, more commonly difficult births, such as those involving prolonged delivery, cephalopelvic disproportion, vacuum extraction, or forceps use. Intrauterine injuries may result from amniocentesis, with discovery at birth. Some common injuries will heal without long-term visual or ocular sequelae (Holden et al., 1992). However, identification of birth-related eye trauma necessitates an ophthalmologic consultation to perform a complete dilated examination, identify all injuries, and assess the need for treatment.

Subconjunctival hemorrhage results from rupture of blood vessels on the surface of the eye. It is distinguished from conjunctival

injection due to an inflammatory or infectious cause by characteristically well-demarcated borders between spots of blood underneath the conjunctiva and completely white sclera directly adjacent to the blood. Subconjunctival hemorrhages will resolve spontaneously with time and do not require treatment. However large diffuse hemorrhages can be a sign of more significant trauma underneath the hemorrhage or within the eye, and a complete eye examination, including dilated fundusoscopic examination, may be indicated. Recurrent subconjunctival hemorrhage could be a sign of a coagulopathy or platelet abnormality, and an appropriate work-up should be pursued in such cases.

Hyphema is the presence of red blood cells in the anterior chamber of the eye (the space between the cornea and the iris), most commonly the result of trauma, including birth trauma. It is often associated with other ocular injuries. Clot or hemorrhage of differing magnitude may be seen on close inspection, ranging from a subtle crescent of blood at the corneoscleral limbus to an eye completely filled with blood, obscuring any view of the structures underneath. The red reflex is commonly abnormal. Hyphema is

a potentially vision-threatening condition and requires close management by an ophthalmologist. The immediate concern is obstruction of the aqueous fluid drainage angle structures, resulting in an acute rise in intraocular pressure (IOP) or acute glaucoma. High IOP is painful enough to cause vomiting in children and adults and may manifest as crying, irritability, grimacing, poor feeding, or emesis in an infant. If the IOP is high enough for any prolonged period, irreversible optic nerve damage can ensue, with permanent vision loss. Corneal blood staining may also occur, which takes many months to clear, and can result in amblyopia.

An open globe injury (ruptured globe) refers to a full-thickness break in the eyewall (e.g., sclera, cornea). These injuries can occur as a laceration or as a rupture, in which pressure is applied to the front of the eye, and the eye wall breaks open at its weakest points, such as the corneoscleral limbus or extraocular muscle insertion sites. Key signs include an obvious break with protrusion of intraocular contents (e.g., the iris), which typically appear brown; extensive subconjunctival hemorrhage; a flat anterior chamber (the iris and cornea have come together); hyphema; vitreous hemorrhage, which may be seen as a poor red reflex; and abnormal eye contour or intraocular foreign body on orbital imaging. An open globe is a surgical emergency.

A *corneal abrasion* is an epithelial defect on the corneal surface. Staining with fluorescein will identify areas of missing epithelium, which appear green under a blue light source and magnification. Treatment includes topical antibiotic ointment and close follow-up to ensure complete healing and to monitor the patient for the development of bacterial keratitis (see the earlier discussion of corneal clouding). In a neonate a corneal abrasion must be taken very seriously, because complications can include the sequential development of keratitis, endophthalmitis, septicemia, and meningitis (O'Keefe et al., 2005).

Other injuries include RHs (see the later discussion); corneal trauma from forceps, resulting in tears of the Descemet membrane, visible as vertical or circumferential lines on red reflex examination, corneal thickening and opacification from edema, and corneal scarring; eyelid or adnexal injuries requiring surgical repair; choroidal rupture, which requires dilated fundus examination for diagnosis; and even traumatic optic neuropathy.

Retinal Hemorrhages and Abusive Head Injury

RH from the birth process is very common. The incidence is estimated to be between 10% and 40% of all newborns, depending on the examiner, time from birth, and specific population studied (Emerson et al., 2001; Hughes et al., 2006; Callaway et al., 2016). The rate in infants delivered with vacuum assistance is even higher, at 75%–78% (Emerson et al., 2001; Hughes et al., 2006). The association between vacuum-assisted delivery and RH supports a role for mechanical trauma to the retinal vessels (e.g., from direct compression of the globe); however, additional factors are likely involved, because head circumference and the duration of labor are not significant factors, and RH occurs after cesarean delivery, albeit at decreased frequency (7%) (Emerson et al., 2001; Callaway et al., 2016). RHs are usually identified by indirect ophthalmoscopy, although an abnormal red reflex may be noted in some severe cases.

The long-term visual consequences of birth-related hemorrhages remain unknown. Central or large hemorrhages can interfere with visual development in some cases (Fig. 108.8A), but the occurrence of significant visual deficits caused by RH is probably low. It is important to understand the characteristics that distinguish birth-related RH from those associated with AHT, as there may be

• **Fig. 108.8** Retinal hemorrhages in neonates. (A) Birth-related hemorrhages. Note the large hemorrhage covering the central macula in this neonate with thrombocytopenia. This patient developed severe myopia and amblyopia. (B) Diffuse intraretinal hemorrhages (dot blot, flame shape, and white centered) secondary to nonaccidental head trauma.

considerable overlap. The great majority of birth-related RHs are intraretinal; subretinal and preretinal hemorrhages are less frequent. Such hemorrhages include superficial flame and deeper blot hemorrhages, and larger hemorrhages may frequently contain white centers, which are a completely nonspecific finding (Emerson et al., 2001; Hughes et al., 2006; Callaway et al., 2016). Although commonly located in the posterior pole of the eye, they may also extend to the mid- and far-retinal peripheries and range in number from a few to too numerous to count (Emerson et al., 2001; Hughes et al., 2006). They may be bilateral, unilateral, or asymmetric.

The preceding characteristics are similar to those of the RH seen in AHT (see the later discussion), although the severity is usually greater in AHT. A key characteristic therefore is the time to resolution of birth-related RH. Most intraretinal hemorrhages clear within the first 2 or 3 weeks after birth, many within the first few days (Emerson et al., 2001; Hughes et al., 2006). In most

series, all intraretinal hemorrhages have cleared by age 4 weeks, whereas preretinal or subretinal hemorrhages may take 6 weeks or more to clear (Emerson et al., 2001). Therefore multiple intraretinal hemorrhages present past 1 month of age should be considered not related to birth. Isolated, resolving intraretinal hemorrhage or persistent preretinal or subretinal hemorrhage past 1 month of age may rarely be related to birth, but this pattern of RH would not at any age by itself be considered specific for any cause, including abuse.

Pediatric AHT is a leading cause of death in infancy. Previous names have included *shaken baby syndrome*, *inflicted or nonaccidental head trauma*, and *inflicted childhood neurotrauma*. AHT is characterized by intracranial hemorrhage with or without RHs and/or additional injuries, including bony fractures. Affected children are less than 3 years of age, with the great majority younger than 1 year (Duhaime et al., 1998; Binenbaum et al., 2009). The mechanism of trauma is believed to be repetitive acceleration–deceleration of an infant's head, with or without blunt impact. RHs are present in 50%–100% of victims of AHT (Duhaime et al., 1998; Binenbaum et al., 2009). The presence of any RH in an infant is highly associated with abuse, and increasing RH severity correlates with increasing likelihood of abuse (Binenbaum et al., 2009; Bhardwaj et al., 2010). In AHT, RH may range from none to a few intraretinal hemorrhages confined to the posterior pole to bilateral, “too numerous to count,” intraretinal, subretinal, and preretinal hemorrhages, extending to the far periphery or ora serrata (termination of the retina) (Levin, 2010; Binenbaum et al., 2014). The hemorrhages may be unilateral or markedly asymmetric. Macular retinal folds and hemorrhagic macular retinoschisis (splitting of the retinal layers) may be seen at the severe end of the spectrum. In comparison, RHs associated with accidental head trauma are typically few in number, intraretinal, and limited to the posterior pole (Bechtel et al., 2004; Binenbaum et al., 2009) (see Fig. 108.8). However, more severe RH and even retinal folds may be seen with unambiguous severe accidental trauma, such as fatal motor vehicle crashes (Kivlin et al., 2008).

In addition to accidental head trauma, the differential diagnosis of RH in infancy includes birth-related RH (see the earlier discussion), coagulopathy, septicemia, leukemia, anemia, and glutaric aciduria. These conditions may be recognized with use of various diagnostic tests and are often distinguishable from the patterns of RH seen in AHT. Studies have demonstrated that prolonged chest compression with cardiopulmonary resuscitation very rarely results in RH, and when present, these RHs are a few isolated posterior pole intraretinal hemorrhages. RHs associated with raised intracranial pressure are limited to small splinter hemorrhages on a swollen optic disc or superficial, flame-shaped, intraretinal hemorrhages adjacent to a swollen optic disc (Binenbaum et al., 2013). Vaccination injections, convulsions, and severe coughing do not cause RH (Binenbaum et al., 2015).

Children with AHT may present with a history of minor blunt head trauma, such as a short fall, or no trauma history at all and exhibit lethargy, seizures, increased or decreased tone, vomiting, poor feeding, breathing difficulties, or apnea (Duhaime et al., 1998). Head CT identifies subdural or subarachnoid hemorrhage, sometimes with a combination of chronic and acute features, but very rarely the findings may initially be normal; brain MRI provides a better look at the soft tissue and brain parenchyma to identify features such as hypoxic–ischemic injury; plain film radiographs may reveal a skull fracture; and a skeletal survey is a critical modality for identifying other bony injuries. Because the history provided is often vague or unreliable, a high index of suspicion and a low

threshold for obtaining diagnostic tests and specialist consultation must be maintained.

Ophthalmologic examination should occur within 48 hours, preferably within 24 hours, because RH can begin to resolve within days (Binenbaum et al., 2016). A dilated fundus examination with an indirect ophthalmoscope is required to adequately visualize the retina. Ophthalmologic consultation should not be delayed because of an inability to pharmacologically dilate the pupils because of neurologic pupil examination checks; the ophthalmologist can still attempt to view a portion of the retina and return for a dilated examination later. It is very important to document the type(s), number, location(s), and laterality of all RHs, by the use of explicit descriptive terms and thorough use of diagrams.

Fundus photographs, for example, those taken with a RetCam camera, should be obtained when possible. Such photographs provide important documentation and are often easily obtained at the time of sedation administered for MRI or other tests. However, the authors stress that the presence of RH is not descriptive enough, and the extent and detailed characteristics of the hemorrhages are vitally important. Cameras may identify and characterize posterior pole RH, but they do not always provide adequate visualization of the retinal periphery and are not a substitute for an indirect examination. RHs have been reported as a result of RetCam use in a premature infant undergoing ROP screening, but not in other circumstances (Adams et al., 2004). Notably, this 25-week-gestational-age infant was less than 34 weeks' PMA at the time of the examination and had immature retinal vasculature, without smooth muscle, elastin, or collagen layers and poor autoregulation, unlike the mature vasculature of a few-months-old infant evaluated for AHT (Adams et al., 2004). Further, other investigators have failed to identify any RHs with the routine use of the RetCam for ROP screening (Azad et al., 2004). Nevertheless, whenever possible an indirect ophthalmoscopic examination should be performed and documented before a contact fundus camera is used.

Visual impairment in children with AHT is thought to be due, most often, to cortical damage. However, persistent macular or vitreous hemorrhage, retinoschisis, and other scarring conditions may result in significant deprivation amblyopia, induced myopia and anisometropic amblyopia, or photoreceptor damage limiting visual function. The overall mortality rate in AHT has been reported to be between 13% and 36% (Barlow et al., 2005). Approximately two-thirds of the survivors have long-term neurologic deficits. In a prospective study of 25 children with a mean follow-up of 5 years, Barlow et al. (2005) found that 68% had neurologic and cognitive impairment, and half of these had severe disabilities and were totally dependent.

Retinopathy of Prematurity

ROP, a disease of the developing retinal vasculature, first became a significant cause of blindness in children in the 1950s with increased survival of premature infants as a result of improved neonatal care, in particular the use of supplemental oxygen in industrialized countries. With restriction of oxygen use in the mid-1950s, there was a reduction in the incidence of blindness from ROP, but this was associated with increased rates of death and cerebral palsy in premature babies. During the late 1960s, despite more accurate methods to monitor oxygen supplementation and improved management of perinatal complications, blindness from ROP began to reemerge because smaller and less mature babies were surviving. Surgical treatment of established disease

ROP, Retinopathy of prematurity.

and improved neonatal care are probably the major factors responsible for the reduction of the incidence of blinding ROP observed during the 1980s and 1990s in developed countries such as the United States (Gibson et al., 1989). However ROP-related blindness continues to be an important public health problem among middle-income countries, in which the capability to save small babies has developed, but oxygen use is often not controlled, and the resources to screen babies for and treat ROP are lacking (Gilbert et al., 2005).

Classification of Retinopathy of Prematurity

The International Classification of Retinopathy of Prematurity (ICROP) was published in 1984 (International Committee for the Classification of Retinopathy of Prematurity, 1984) and expanded in 1987 (International classification of ROPm, 1987), providing a standard nomenclature for the clinical findings and staging of ROP. As shown in Table 108.2, this classification takes into account four components of the ocular findings: anterior–posterior location of the retinopathy (zone), severity (stage), extent of the disease at the circumference of the vascularized retina (in clock hours), and the presence or absence of so-called plus disease. *Plus disease* is defined as engorged and tortuous vessels of the posterior pole and indicates a more serious form of ROP. The ROP status of an eye is determined by the highest stage and the lowest zone observed, along with the noting of the presence or absence of plus disease.

In ICROP the retinal surface is divided into three concentric “zones” centered on the optic nerve (Fig. 108.9). Most severe retinopathy occurs in zone I or posterior zone II, most retinopathy occurs in zone II, and ROP that occurs in zone III tends to be mild. The severity of retinopathy is designated on a scale of 1 to 5 by “staging” of the retinopathy at the junction between vascular and avascular retina (Fig. 108.10). The first two stages indicate mild and moderate disease; the extension of vessels into the vitreous indicates stage 3 ROP, a more serious disease. Stages 4 and 5

• **Fig. 108.9** Retina of the right eye (RE) and left eye (LE) showing zone borders and clock hours used to describe the location and extent of retinopathy of prematurity. N., Nerve. (Reproduced from *Arch Ophthalmol.* with permission.)

indicate the presence of retinal detachment. The term *plus disease*, a clinical diagnosis made by comparison with reference photographs used in clinical treatment trials in the United States (Good et al., 2005), indicates marked tortuosity and/or dilation of the peripapillary arterioles and venules in at least two quadrants. *Pre-plus disease* designates the presence of vessels that are not normal appearing but are not sufficiently abnormal to be designated as plus disease. Other signs that frequently accompany serious ROP include vitreous haze, iris vascular engorgement, and pupillary rigidity, but these signs are not required to make the diagnosis of plus disease.

In 2005 aggressive posterior ROP was added to ICROP, defining the observation of a particularly aggressive form of ROP observed with increasing frequency in the smallest premature babies and that may be more difficult to recognize, because the peripheral retinopathy is not as remarkable even though the posterior pole vascular abnormalities of dilation and tortuosity are quite marked

• **Fig. 108.10** Fundus photograph showing the ridge between vascularized and avascular retina characteristic of stage 2 retinopathy of prematurity (large arrow). Stage 3 retinopathy of prematurity is present in the left-hand portion of the photograph (small arrow).

(International Committee for the Classification of Retinopathy of Prematurity, 2005).

Prevalence and Incidence of Retinopathy of Prematurity

Large natural history studies have shown that, in most cases, ROP begins at 31 to 33 weeks' PMA (Fielder et al., 1992; Good et al., 2005) with progression during the next 2 to 5 weeks. Spontaneous regression occurs in eyes with stage 1 and stage 2 ROP and early stage 3 ROP (Palmer et al., 1991; Repka et al., 2000). Blindness or severe visual impairment commonly results from progression of the retinopathy to retinal detachment or severe distortion of the posterior retina.

ROP occurs in most babies with birthweights less than 1500 g (very low birth weight [VLBW]), with an even greater proportion of babies developing ROP in the less than 1000 g birthweight category (extremely low birth weight, ELBW) and in the less than 750 g birthweight category (Fielder et al., 1992; Good et al., 2005). As neonatal services continue to improve, a greater proportion of VLBW and ELBW babies survive, with a resultant increase in the population of babies at risk (Gilbert et al., 2005).

Pathogenesis of Retinopathy of Prematurity

ROP develops as a result of poor retinal vascularization, leading to retinal hypoxia and pathologic neovascularization. With premature birth, relative hyperoxia, exacerbated by exogenous oxygen supplementation, damages existing retinal blood vessels and suppresses retinal secretion of vascular endothelial growth factor (VEGF), a hypoxia-induced vasoactive molecule responsible for normal and pathologic blood vessel development and growth in the body (Pierce et al., 1996; Hellstrom et al., 2001; Smith et al., 2003, 2008). Premature birth also results in a loss of maternal insulin-like growth factor (IGF)-1, a somatic growth factor secreted by the liver but derived primarily from maternal sources until the third trimester (Hellström et al., 2003). As retinal development progresses, relative hypoxia ensues, but VEGF-induced vessel growth is suppressed by low serum levels of IGF-1 (Hellstrom et al., 2001). Finally, as the infant's innate production of IGF-1 rises after 30 to 33 weeks' PMA, heightened local concentrations of VEGF are activated, causing pathologic neovascularization.

Prediction of Retinopathy of Prematurity

Following from the pathologic sequence described previously, important risk factors for ROP include the degree of prematurity (early gestational age at birth and low birth weight); hyperoxia early in the postnatal course, especially from excessive oxygen supplementation; and low postnatal serum IGF-1 level in the postnatal period up to 33 weeks' PMA (Perez-Munuzuri et al., 2010). Slow postnatal weight gain is a reliable surrogate measure for serum IGF-1 levels (Hellstrom et al., 2001; Hellström et al., 2009, 2010). Numerous other factors have been associated with ROP, such as sepsis, acidosis, nutritional deficiencies, and necrotizing enterocolitis; however, many of these factors may influence serum IGF-1 levels in a common mechanistic pathway (Löfqvist et al., 2006).

Current screening guidelines focus solely on gestational age at birth and birthweight as predictors of ROP. Because slow postnatal weight gain is highly correlated with IGF-1 levels and has been shown to be a reliable predictor of subsequent ROP development (Löfqvist et al., 2006, 2009a; Wu et al., 2010; Binenbaum et al., 2011), multiple postnatal weight gain predictive models have been developed in an effort to improve the efficiency of ROP screening in highly developed NICU systems. These models include WINROP (Weight, Insulin-like growth factor-I, Neonatal, ROP) (Wu et al., 2012; Lundgren et al., 2013), ROPScore (Eckert et al., 2012), the Premature Infants in Need of Transfusion ROP model (Binenbaum et al., 2011), the Children's Hospital of Philadelphia ROP model (Binenbaum et al., 2012), and the Colorado ROP model (Cao et al., 2016). All of these models have exhibited very high sensitivity for predicting ROP, while reducing the number of infants who would have required examinations when applied in retrospective studies. Soon, slow postnatal weight gain could be incorporated into current screening guidelines if the ongoing larger validation studies provide precise estimates of sensitivity for predicting severe ROP (Binenbaum et al., 2013).

Prevention of Retinopathy of Prematurity

Medical treatments designed to prevent ROP hold promise to markedly decrease development of serious ROP. Interventions such as steroids given to expectant mothers immediately before preterm birth and surfactant administered to the neonate shortly after birth decrease the incidence of respiratory distress syndrome, which would be expected to decrease the incidence of serious ROP. However, these medical advances have also increased the survival rate of VLBW babies (Soll, 2000). Currently there are no interventions that have been proven to prevent the development of severe ROP in VLBW infants. Strict regulation of the use of supplemental oxygen in the first few weeks of life has been recommended as a strategy to reduce the incidence of severe ROP; however, this can result in increased morbidity and mortality. In an effort to determine the optimal oxygen saturation target for premature infants, several randomized clinical controlled trials have been conducted recently: the Surfactant, Positive Pressure, and Oxygenation Randomized Trial (SUPPORT) in the United States, the Canadian Oxygen Trial (COT), and the Benefits of Oxygen Saturation Targeting II (BOOST II) trial conducted in the United Kingdom, Australia, and New Zealand. In a metaanalysis of these three trials, the risk of developing severe ROP was not significantly different between the restricted oxygen group (SpO₂ targets of 85%–89%) and the liberal oxygen group (SpO₂ targets of 91%–95%) (risk ratio [RR] 0.72, 95% confidence interval [CI] 0.50–1.04); however, sensitivity analysis using a fixed-effect model (where BOOST II had a larger weight assigned) moved the estimated effect in favor of restricting

oxygen use (RR 0.75, 95% CI 0.63–0.88). Higher frequencies of necrotizing enterocolitis and death before hospital discharge were, however, found in the restricted oxygen group. The study authors concluded that the level of certainty for the ROP outcome is low, and there is still significant uncertainty about the optimal target range for SpO₂ (Manja et al., 2015).

Vitamin E supplementation, dietary supplementation with omega-3 polyunsaturated fatty acids, systemic and topical beta-blockers and intravenously administered IGF-1 and IGF-binding protein are currently under investigation (Raju et al., 1997; Löfqvist et al., 2009b; Bührer, 2015).

Detection of Serious Disease

Because the benefit of treatment of serious ROP has been shown in randomized clinical trials (*Cryotherapy for Retinopathy of Prematurity Cooperative Group*, 1990, 1991, 2001; *Early Treatment for Retinopathy of Prematurity Cooperative*, 2003), it is essential to identify the at-risk baby so that timely examinations can be performed to prevent blindness or at least decrease its likelihood. In the United States the recommended guidelines for detection of serious ROP indicate that diagnostic examinations should be performed on infants with birthweights less than or equal to 1500 g or of 30 weeks' gestation, along with babies in the 1501–2000-g birthweight group thought to be at high risk by the neonatologist (Reynolds et al., 2002; Fierson et al., 2013). In Latin American countries and in urban centers of newly industrializing countries in Asia and eastern Europe, the same screening criteria do not apply, because evidence suggests that larger, older babies are also at risk in these settings, and national or regional guidelines need to be developed (Azad and Chandra, 2003; Trinavarat et al., 2004; Fortes Filho et al., 2007; Vedantham, 2007; Varughese et al., 2008).

The first examination should generally occur at 31 weeks' PMA or chronologic age of 4 weeks, whichever occurs later (Reynolds et al., 2002; American Academy of Pediatrics Section on Ophthalmology et al., 2013). Examinations usually continue on an every-other-week basis unless ROP develops, at which time examination frequency may be increased depending on the severity of the disease. In general, examinations continue until ROP is observed to regress, ROP progresses to treatment severity, or vessels are observed on at least two occasions to have progressed into zone III in the absence of ROP. Coordination of this schedule among neonatal care providers, ophthalmologists, nursing staff, and parents is essential. If outpatient appointments are not kept or proper information is not conveyed when the baby is transferred to another facility, potentially treatable disease may be missed, with disastrous consequences (Mills, 2009).

Telemedicine and Retinopathy of Prematurity

Although direct examination by an ophthalmologist experienced in examining babies at risk of ROP continues to be the optimal standard of care, retinal digital imaging has emerged as a promising modality for ROP screening. The increased workload because of the increase in survival of premature infants worldwide (Gilbert et al., 2005) coupled with the reduced availability of ophthalmologists with sufficient ROP experience has required the development of alternative screening approaches. The published sensitivity of digital fundus imaging as a screening technique for ROP ranges from 57% to 100% (with wide 95% CIs) when compared with the reference standard (indirect ophthalmoscopy). In 2015 the American Academy of Pediatrics and the American Academy of Ophthalmology published a review of the current status of telemedicine in ROP (Fierson et al., 2015) and concluded that retinal

digital imaging is a reasonable alternative to but not a substitute for direct examination by an on-site ophthalmologist. However, more studies are needed to determine the overall validity of the approach.

Notwithstanding the lack of consensus, ROP telemedicine is becoming increasingly available in the United States and other countries. The Stanford University Network for Diagnosis of Retinopathy of Prematurity (SUNDROP) has reported its experience evaluating infants meeting ROP screening criteria with images taken in the NICU by trained nurses and remotely evaluated by an ophthalmologist. In this program all infants undergo one direct examination after discharge. In a recent report of 608 infants examined during a 6-year period, sensitivity was reported as 100%, with specificity and a negative predictive value of 99.8% and 100%, respectively (Wang et al. 2015). Comparable results were reported by Weaver and Murdock (2012) on infants imaged in rural Montana where there was no ophthalmologist within 200 miles of the hospital. As in the SUNDROP program, all infants who underwent telemedicine evaluations also underwent an outpatient diagnostic examination within 2 weeks of discharge.

Recently, the results of the National Eye Institute of the NIH-sponsored Telemedicine Approaches to Evaluating Acute-Phase ROP (e-ROP) study were released. This is the largest study to date, with more than 1200 infants with birthweights less than 1251 g enrolled (Quinn et al., 2014). In e-ROP, nonphysicians obtained a series of wide-field images from each eye using the RetCam Shuttle (Clarity Medical System, Pleasanton, California, USA). Image sets were then uploaded to a central server for grading by nonphysician readers who had undergone extensive training (Daniel et al., 2015). The sensitivity of detecting ROP that warranted referral on image grading was 90% (95% CI 85%–94%), the specificity was 87% (95% CI 84%–90%), and the negative predictive value was 97.3% in this study. The reported adverse event rate (apnea, bradycardia, emesis, and reintubation shortly after e-ROP procedures) was noted in 4.9% of infants and 0.8% of study procedures. Adverse events were more likely to occur when the infant was receiving mechanical ventilation, regardless of whether the procedure was an eye examination or retinal imaging.

Other reports have focused on the logistics of the implementation of ROP telemedicine in various settings throughout the world. The Karnataka Internet Assisted Diagnosis of Retinopathy of Prematurity model provides ROP screening in more than 80 units in the Karnataka region of India, using technicians who obtain and grade the images at the bedside and report the need for an evaluation to an ophthalmologist, who can then give treatment if needed (Vinekar et al., 2014). This model has demonstrated that ROP screening services can be provided in regions of the world with limited access, but it is still highly dependent on the availability of ophthalmologists to provide treatment and high levels of training and technical expertise. Gilbert et al. (2016) have stressed the need to shift the emphasis on examination to remote imaging in low- and middle-income regions of the world where ROP remains a leading cause of childhood blindness yet the expertise, availability and physical resources for adequate ROP screening are quite limited. In these countries this approach has the potential to expand services dramatically as increasingly small birthweight and low gestational age infants survive worldwide. In more developed healthcare systems the potential role of telemedicine as a stand-alone screening tool is currently undergoing intensive scrutiny, highlighting a number of complex issues for implementation (limited number of available imaging systems, high cost of equipment; personnel training

requirements, quality control issues, coordination of services, accountability, etc.) that should be resolved before a successful and safe implementation of such a screening modality.

Treatment of Retinopathy of Prematurity

Laser ablation of the peripheral avascular retina can prevent progression to blinding disease in patients with severe ROP and is currently the standard of care for treatment. The evidence of treatment effectiveness and the indications for treatment (severity level) have evolved through the last 30 years as multiple multicenter clinical trials have been conducted to evaluate different treatment modalities and preventative strategies. Landmark studies include the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study, the Early Treatment for Retinopathy of Prematurity (ET-ROP) study, the Supplemental Therapeutic Oxygen for Prethreshold Retinopathy of Prematurity (STOP-ROP) study, the Effects of Light Reduction on Retinopathy of Prematurity study, and the Bevacizumab Eliminates the Angiogenic Threat for Retinopathy of Prematurity (BEAT-ROP) study.

Current treatment guidelines are based on the findings of the ET-ROP study, so treatment intervention is recommended on the development of “type 1” prethreshold ROP, defined as *any stage with plus disease in zone I, stage 3 without plus disease in zone I, or stage 2 or 3 with plus disease in zone II*. It is important to highlight that the number of clock hours of disease previously used in the CRYO-ROP definition of “threshold” is not considered anymore, and treatment should not be delayed until “threshold” ROP is reached.

Today, in most centers, laser photocoagulation is preferred because of its advantages over cryotherapy, including less discomfort intraoperatively and postoperatively, less pigmentation resulting from the therapy, and direct visualization of the area during treatment. For advanced disease (i.e., retinal detachment, stages 4 and 5), studies have shown mixed results, but treatment is in general much less successful (Jabbour et al., 1987; Hirose et al., 1993; Trese, 1994; Andrews et al., 1999). For eyes with total detachment, good functional outcome is not likely to be achieved (Quinn et al., 1991; Hirose et al., 1993; Quinn et al., 1996). Laser treatment concerns include the risk of intubation and sedation frequently required for the procedure, the prevalence of high myopia and peripheral visual field reduction, and poor visual acuity outcomes in patients with posterior or aggressive ROP.

In the past decade there has been increased interest in the use of anti-VEGF drugs for the treatment of ROP. The effectiveness of these drugs, reported in multiple observational studies, was confirmed in a multicenter randomized controlled trial (Mintz-Hittner et al., 2011), where intraocular bevacizumab injection was shown to result in a lower retreatment rate at 54 weeks’ PMA than laser photocoagulation in babies with zone I and posterior zone II type 1 ROP (6% vs 42% in the zone I subgroup). As a result, intravitreal injections of bevacizumab and other anti-VEGF agents (e.g., ranibizumab, aflibercept) are being considered more and more often as a first-line treatment alternative, in particular for eyes with zone I ROP because laser photocoagulation is relatively ineffective in decreasing retinal detachment in those eyes. At the 6-year outcome of the ET-ROP study, more than 30% of zone I type 1 eyes had visual acuity of 20/200 or less, and more than 20% had macular folds or retinal detachments. The BEAT-ROP study reported that at 2.5 years children treated with bevacizumab have a significantly lower incidence of high myopia than those treated with laser ablation. Very high myopia occurred in 3.8% of zone I eyes and 1.7% of zone II eyes that received bevacizumab

compared with 36.4% of zone I eyes and 51.4% of zone II eyes that received laser treatment ($P < .001$) (Geloneck et al., 2014). However, visual function outcomes have not been reported yet, and long-term systemic effects have not been adequately studied. The concerns over the ocular and systemic antiangiogenic consequences of these drugs are based on the fact that VEGF is a critical factor in neurodevelopment as well as vasculogenesis in other developing organ systems, including the lungs and kidneys. It has been shown that systemic absorption of the medication after intraocular injection is significant and leads to a reduction in systemic VEGF levels, lasting at least 60 days after injection.

The BEAT-ROP (bevacizumab) trial was too small to assess safety and effects on future development of brain and other tissues. In addition, subsequent reports described late and sometimes severe recurrences with the use of bevacizumab monotherapy that might not have been captured in the original trial. Lepore et al. (2014) reported vascular and macular abnormalities detected on fluorescein angiogram 9 months after ROP treatment with bevacizumab. More recently, reports from Canada and Taiwan described increased risk of motor impairment in ROP patients treated with bevacizumab (Lien et al., 2016; Morin et al., 2016; Quinn and Darlow, 2016). In the Canadian study, the authors attempted to control for many possible factors that could affect neurocognitive development, such as SNAP II scores, bronchopulmonary dysplasia, sepsis, intraventricular hemorrhage, gestational age, and maternal education, and found that at age 18 months, bevacizumab-treated infants were two to three times more likely to display unfavorable developmental outcomes compared with those that underwent laser ablation. However, these studies are still limited by their observational retrospective nature, which may not adequately control for other unknown possible confounders. It is acknowledged that ROP in itself is an independent predictor of adverse long-term neurodevelopment, and in many instances the indication for anti-VEGF treatment over laser ablation is confounded by the severity of disease or the underlying systemic condition of the infant (confounding by indication). Nevertheless, this early evidence increases the concern regarding the long-term safety of anti-VEGF treatment and calls for more research in this area. When one is considering all the treatment options, careful consideration and a thorough discussion with the parents and neonatology team are recommended. None of the anti-VEGF drugs have been approved by the US Food and Drug Administration for the treatment of ROP, and therefore detailed consent for their off-label use must be obtained. Premature infants treated with anti-VEGF injections must be followed up very closely for extended periods, at least until complete retinal vascularization is observed.

Common Ophthalmic Manifestations of Systemic Diseases

Tables 108.3–108.5.

Role of the Neonatal Healthcare Provider

Neonatal and primary pediatric healthcare providers clearly play a central role in the ophthalmologic care of the newborn and young infant. The first few weeks after birth constitute a critical period of visual development in the brain, and the opportunity and responsibility to screen the newborn for ocular disease rests in the hands of those providers, whether neonatologist, pediatrician, family physician, or nurse practitioner. With use of the I-ARM

| Etiologic Disorder | Inheritance | Ophthalmic Manifestations |
|---|---|--|
| Aicardi syndrome | X-linked dominant disorder characterized by triad of callosal agenesis, infantile spasms, and chorioretinal lacunae OMIM 304050 | Bilateral or unilateral, multiple, chorioretinal lacunae (most constant feature), optic disk/retinal/iris colobomas, optic nerve head hypoplasia, microphthalmos, retinal detachment (Aicardi, 2005) |
| Alagille syndrome (1 and 2) | Autosomal dominant disorder characterized by neonatal jaundice secondary to hepatic cholestasis OMIM 118450 and 610205 | Posterior embryotoxon, optic disc drusen, and retinal pigmentary changes sometimes in associations with rod–cone dystrophy |
| Albinism | Heterogenous disorder of melanin metabolism associated with abnormal development of the retina and visual pathways Ocular forms: type 1 (X-linked) Oculocutaneous forms: types 1–4, Hermansky–Pudlak and Chediak–Higashi syndromes (autosomal recessive, autosomal dominant) More than 13 genes involved | Reduced vision, delayed visual maturation, nystagmus, strabismus, iris transillumination, fundus hypopigmentation, foveal hypoplasia, misrouting of optic nerve fibers, anomalous optic chiasm |
| CHARGE syndrome (coloboma, heart defect, choanal atresia, retarded growth, genital hypoplasia, and ear anomalies) | Nonrandom cluster of congenital abnormalities Mutation of <i>CHD7</i> on 8q12.1 (Vissers et al., 2004 ; Jongmans et al., 2006) OMIM 214800 | Unilateral or bilateral uveal colobomas (retinal more frequent than iris), microphthalmos, Bell palsy |
| 22q11.2 deletion syndrome | Contiguous gene deletion syndrome (encompasses DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly–face syndromes) Autosomal dominant | Posterior embryotoxon, tortuous retinal vessels, eyelid hooding, strabismus, ptosis, sclerocornea (Forbes et al., 2007 ; Binenbaum et al., 2008) |
| Down syndrome | Trisomy 21 OMIM 19605 | NLDO, refractive errors, nystagmus, strabismus, retinal abnormalities, keratoconus, cataracts (Creavin and Brown, 2009) |
| De Morsier syndrome (septo-optic dysplasia) | Heterogeneous disorder defined by the combination of optic nerve hypoplasia, pituitary dysfunction, and midline abnormalities of the brain (absence of the corpus callosum and septum pellucidum) OMIM 182230 | Optic nerve hypoplasia (unilateral or bilateral), strabismus, nystagmus, optic chiasm hypoplasia. Severe cases may have microphthalmos or anophthalmos |
| Galactosemia (classic) | Metabolic disorder caused by mutation in the galactose 1-phosphate uridylyltransferase gene OMIM 230400 | Congenital cataracts (“oil-droplet cataracts”) |
| Goldenhar syndrome (oculoauriculovertebral dysplasia, hemifacial microsomia) | Craniofacial birth defect involving first and second branchial arch derivatives OMIM 164210 | Epibulbar dermoid (unilateral or bilateral), coloboma of the upper lid, ptosis, strabismus, microphthalmos, nasolacrimal duct obstructions |
| Homocystinuria | Autosomal recessive metabolic disorder caused by cystathionine β -synthetase deficiency OMIM 236200 | Progressive ectopia lentis (lens subluxation), pupil block glaucoma, progressive myopia, optic atrophy, retinal detachment (Harrison et al., 1998) |
| Kabuki syndrome | Congenital mental retardation syndrome OMIM 147920 | Long palpebral fissures with eversion of the lateral third of the lower eyelids, ptosis, strabismus |
| Möbius sequence | Sporadic disorder characterized by congenital facial weakness and abduction deficits OMIM 157900 | Abnormal tearing, esotropia with limited abduction (unilateral or bilateral CN VI palsy), horizontal gaze palsy, other CN palsies (III, IV, V), ptosis |
| Myasthenic syndromes (congenital and neonatal myasthenia gravis) | Neuromuscular disorders. The congenital form is a nonautoimmune autosomal dominant disorder. The neonatal form is secondary to maternal antibodies | Bilateral or unilateral ptosis, any pattern of strabismus, limited ocular motility |
| Incontinentia pigmenti (Bloch–Sulzberger syndrome) | X-linked dominant disorder with characteristic skin lesions OMIM 308300 | Strabismus, nystagmus, cataracts, optic atrophy, corneal abnormalities, retinovascular abnormalities (may resemble ROP), retinal detachment |

Continued

**TABLE
108.3****Ophthalmic Manifestations of Systemic Diseases With Neonatal Findings—cont'd**

| Etiologic Disorder | Inheritance | Ophthalmic Manifestations |
|---|--|--|
| PHACES syndrome (<i>posterior fossa</i> brain malformations, <i>hemangiomas</i> of the face, <i>arterial cerebrovascular anomalies</i> , <i>cardiovascular anomalies</i> , <i>eye anomalies</i> , <i>sternal defects</i>) | Heterogeneous associations that occur in patients with large segmental cervicofacial hemangiomas OMIM 606519 | Microphthalmos, Horner syndrome, retinal vascular abnormalities, optic nerve atrophy, iris hypoplasia, cataracts, sclerocornea, lens coloboma, strabismus, choroidal hemangiomas, congenital third nerve palsy, morning glory deformity, and glaucoma (Coats et al., 1999; Hartemink et al., 2009) |
| Stickler syndrome (hereditary arthro-ophthalmopathy) (1 and 2) | Autosomal dominant disorder of collagen synthesis OMIM 108300 and 604841 | Congenital myopia, vitreous abnormalities, cataracts, retinal detachment |
| Trisomy 13 | Chromosomal abnormality most consistently associated with severe ocular defects | Anophthalmos, cyclopia, microphthalmos, uveal colobomas, cataracts, corneal opacities, retinal dysplasia, intraocular cartilage |
| Trisomy 18 | Chromosomal abnormality with frequent ocular defects | Microphthalmos, short palpebral fissures, ptosis, hypertelorism, iris coloboma, corneal opacities, cataracts |
| Tuberous sclerosis | Autosomal dominant multisystem disease characterized by hamartomatous growths in multiple organs OMIM 191100 and 605284 | Retinal hamartomas, vitreous hemorrhage, chorioretinal punched-out lesions, papilledema, optic nerve atrophy, strabismus (Rowley et al., 2001) |

CN, Cranial nerve; NLDO, nasolacrimal duct obstruction; OMIM, Online Mendelian Inheritance in Man; ROP, retinopathy of prematurity.

**TABLE
108.4****Eye Manifestations of Intrauterine and Perinatal Infections**

| Infection | Ophthalmic Findings | Diagnosis |
|--|--|--|
| Toxoplasmosis (<i>Toxoplasma gondii</i>) | Retinitis, vitritis, choroiditis and anterior uveitis; flat atrophic retinal scars | Present in 75% of newborns with toxoplasmosis, 10% have only ocular findings |
| Syphilis (<i>Treponema pallidum</i>) | Chorioretinitis (salt-and-pepper appearance or pseudoretinitis pigmentosa), anterior uveitis, glaucoma, interstitial keratitis | Clinical ELISA Positive IgM assay result (maternal IgM does not cross the placenta) |
| Rubella | Nuclear cataracts, glaucoma, uveitis, microphthalmos, retinopathy with salt-and-pepper appearance, pseudoretinitis pigmentosa | Bilateral interstitial keratitis is the classic ophthalmic finding; it occurs in 10% of patients but manifests itself later in childhood or adulthood. |
| Cytomegalovirus infection | Retinochoroiditis, optic nerve atrophy, microphthalmos, cataracts, uveitis, strabismus (Coats et al., 2000) | 50% of children with rubella have ocular findings, bilateral 70% Severe postoperative inflammation after cataract surgery |
| Herpesvirus infection (HSV 1 and 2, EBV) | Vesicular skin lesions, keratoconjunctivitis, retinochoroiditis, cataracts | Most common intrauterine viral infection in the United States Only 10% of infants show clinical features of CMV infection, with ophthalmologic abnormalities in less than 30% of these. |

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; ELISA, enzyme-linked immunosorbent assay; FTA-ABS, fluorescent treponemal antibody absorption; HSV, herpes simplex virus; IgM, immunoglobulin M; PCR, polymerase chain reaction; VDRL, Venereal Disease Research Laboratory.

TABLE 108.5 Eye Findings After In Utero Exposure to Teratogens

| Teratogen | Ophthalmic Manifestations |
|--|---|
| Alcohol (fetal alcohol syndrome) | Short palpebral fissures, microphthalmos, epicanthal folds, optic nerve head hypoplasia, tortuosity of retinal vasculature, strabismus, cataracts (Strömland and Hellström, 1996) |
| Cocaine | Optic nerve abnormalities, delayed visual maturation, ROP-like fundus abnormalities (Teske and Trese, 1987), prolonged eyelid edema (Good et al., 1992) |
| Anticonvulsants (fetal hydantoin syndrome) | Ptosis, trichomegaly, hypertelorism, strabismus, retinal coloboma, microphthalmos, optic nerve head hypoplasia (Hoyt and Billson, 1978; Hampton and Krepostman, 1981) |
| Methadone | Nystagmus, delayed visual development, abnormal VEPs at birth (McGlone et al., 2013, 2014) |
| Warfarin and coumadin | Optic atrophy, cataracts, anterior segment dysgenesis, microphthalmos (Hall et al., 1980) |
| Thalidomide | Strabismus, Duane syndrome, ptosis, paradoxical gustulacrimal tearing, Möbius sequence (Miller et al., 2009) |
| Misoprostol | Möbius sequence (Miller et al., 2009) |

ROP, Retinopathy of prematurity; VEPs, visual evoked potentials.

framework as a guide, referral to a pediatric ophthalmologist should be made for any abnormality or asymmetry in an atomic structure or visual function. Some conditions require a particularly urgent referral, such as an abnormal red reflex, cloudy cornea, and ocular infection or trauma. Identification of a sight-threatening cataract or life-threatening retinoblastoma is most commonly made by an astute pediatric clinician in the NICU, nursery, or primary care office who carefully evaluates the red reflex in both eyes. In the case of neonatal conjunctivitis, diagnostic cultures and treatment should be undertaken without delay, but ophthalmology consultation is still necessary to rule out corneal or intraocular involvement. Premature infants at risk of ROP are a particularly vulnerable population. It is the neonatologist's clinical and medicolegal responsibility to arrange timely diagnostic ROP examinations in the NICU and to communicate to parents the absolute necessity of keeping ophthalmologist outpatient appointments after the infant has been discharged from the hospital. Such appointments should be scheduled before discharge. A delay in care by even 1 week could result in a disastrous visual outcome.

The neonatal healthcare and primary care pediatric teams should provide ongoing eye-related education and support. Reducing the risk of pediatric AHT is one important topic to be discussed with all parents and caregivers. Viewing of educational videos on shaken baby syndrome is mandatory in an increasing number of municipalities, and reductions in AHT incidence have been demonstrated. Pediatricians should discuss crying and parental stress at office visits during the first few months of life; the Period of PURPLE Crying educational materials (<https://www.dontshake.org/purple-crying>) are very useful in this regard. Pediatricians can also provide support for the families of children with visual impairment, ensuring early, anticipatory referral to state commissions for the blind and

early intervention services, and ongoing encouragement for parents to maximally utilize such resources when they are available.

Rapid visual development occurs in the months following the neonatal period. Primary care eye examinations and vision assessments continue to be vital for the detection of conditions that may result in visual impairment or blindness, lead to problems with school or social performance, signal the presence of a serious systemic disease, or threaten the child's life. Children should have an eye examination at each well-child visit. Children at high risk of eye disease should be referred for examination by a pediatric ophthalmologist, including children with a history of prematurity or metabolic or genetic diseases; significant developmental delay or neurologic problems; systemic diseases associated with eye abnormalities; a family history of retinoblastoma, childhood cataracts or glaucoma, inherited retinal disorders, or blindness in childhood; and those whose parents needed glasses at a very young age.

Ear and Hearing Disorders

BETTY VOHR

KEY POINTS

- Hearing loss is one of the most common congenital abnormalities, occurring in approximately 1.5–2 per 1000 newborns.
- Hearing loss may be present at birth or have delayed onset.
- A comprehensive workup is indicated to identify if the etiology is related to genetic or nongenetic causes and whether the hearing loss is progressive or associated with other abnormalities.
- Early diagnosis and intervention within the first 6 months of life provide the best opportunity for normal language development.

Normal Hearing

To understand the spectrum of permanent and transient hearing disorders that can be identified, it is necessary to understand the normal hearing pathway, which consists of transmission of sound energy from the environment via the outer ear through the middle ear, inner ear, auditory nerve, brainstem, and, finally, the temporal lobe cortex, where the sound's electrical energy is interpreted as language (Table 109.1). Dysgenesis, disruption, or injury at any point in the pathway may result in a hearing loss that can have its onset in fetal life or during childhood. The auditory pathway develops embryologically very early in gestation. The inner ear develops first, at about 22 days, and is derived from the otic placodes on either side of the developing head. The middle ear and ossicles derive from the first and third pharyngeal pouches and begin to develop at about day 33. The outer ear develops from the dorsal portion of the first pharyngeal cleft. As a result, congenital hearing loss is often seen in conjunction with structural abnormalities of the head, eyes, ears, nose, and throat. In fact, the odds of having a hearing loss is significantly increased if a preauricular skin tag or pit are present (Roth et al., 2008). Atresia or microtia of the pinna are also strongly associated with a permanent hearing loss. Table 109.2 shows the area of pathology associated with the types of hearing loss. A standard medical assessment for every newborn/child should include both a family history of hearing loss and a comprehensive physical examination for minor or major congenital abnormalities and syndromes associated with hearing loss (Wang et al., 2001). The primary provider should be familiar with risk factors associated with hearing loss, particularly a family history of permanent hearing loss. Approximately 50% of children with permanent hearing loss, however, will not have associated stigmata. Every physical examination in childhood should include an evaluation for the presence of transient middle ear fluid. Once

a child is diagnosed with a permanent hearing loss by an audiologist, additional consultation with ophthalmology, otolaryngology, genetics, and developmental behavioral specialists and a parent support group are recommended to ensure that both the hearing loss and associated diagnoses and challenges are addressed (American Academy of Pediatrics, 2007).

Permanent Hearing Loss—The Challenge

Hearing loss is one of the most common congenital abnormalities, occurring in approximately 1.5–2 per 1000 newborns. Subgroups of infants with risk factors for hearing loss, especially those requiring neonatal intensive care unit (NICU) care, are at increased risk of hearing loss (Vohr et al., 2000; Gaffney et al., 2010). When undetected, permanent hearing loss in infants is associated with significant delays in language development, literacy, and academic success (Yoshinaga-Itano et al., 2001; Moeller et al., 2007; Harrington et al., 2010). Before newborn screening, children in the United States in the 1980s who were deaf or hard of hearing achieved reading comprehension skills at the third grade level at the time of graduation from high school (Schildroth and Karchmer, 1986). A method of early identification trialed in the 1980s was the use of a high-risk register. Physicians would be informed by the birthing hospital of infants who were considered high risk for hearing loss. However, approximately 50% of infants with a permanent hearing loss identified in the newborn period do not have a known risk factor for hearing loss. Newborns were not routinely screened with technology for hearing loss at the time, because there was no effective physiologic method available. This changed after a demonstration project (White et al., 1993) in Rhode Island, funded by the Department of Education and Health and Human Services in 1990–1991, which demonstrated the feasibility of a newborn hearing screening with a new objective physiologic technique, called otoacoustic emissions (OAE). This was followed in 1993 by a National Institutes of Health consensus conference recommending universal newborn hearing screening (NIH Consensus Statement, 1993). Data from the Centers for Disease Control (CDC) indicate that in 2013 more than 97% of newborns were screened in the United States. http://www.cdc.gov/ncbddd/hearingloss/2013-data/2013_ehdi_hsf_summary_e.pdf.

Hearing Disorders

A hearing loss is secondary to interference in the transmission of sound from the outer ear (pinna and ear canal) to the middle ear

TABLE 109.1 Anatomy of the Normal Hearing Pathway

| Structure | Components | Function |
|---|---|--|
| Outer ear | Pinna/auricle, ear canal and the outer layer of the tympanic membrane | Sound waves travel through the air and are conducted through the ear canal to the tympanic membrane where vibrations enter the middle ear. |
| Middle ear | Three ossicles (malleus, incus, and stapes) | Vibrations enter the middle ear and are amplified and transmitted via the ossicles to the fluid within the cochlea (inner ear). Acoustic energy in air is converted to compression waves in fluid in the cochlea. |
| Inner ear | Cochlea Vestibular system | The cochlea converts sound pressure patterns into electrochemical impulses that are passed on to the auditory nerve. A part of the cochlea, the organ of Corti, consists of sensory epithelium and hair cells, which transform fluid waves to nerve signals that regulate balance. |
| Eighth cranial nerve Vestibulocochlear nerve contains both the auditory nerve and the vestibular nerve | Auditory nerve is also called the acoustic nerve or cochlear nerve | The auditory nerve carries auditory sensory information from the cochlea to the brainstem. The vestibular nerve transmits sensory information. |
| Brainstem | Superior olive, to inferior colliculus, to thalamus | Continued transmission of electrical energy on journey to temporal lobes |
| Temporal lobes | Superior temporal gyrus and transverse temporal gyrus (Heschl gyrus) | Sounds are processed and interpreted as language. |

TABLE 109.2 Types of Hearing Loss

| Type | Characteristics |
|--|--|
| Sensorineural | Pathology involving the eighth nerve, outer hair cells, and inner hair cells of the cochlea that impairs neuroconduction of sound energy to the brain stem |
| Permanent conductive | An anatomic obstruction of the outer (atresia) or middle ear (fusion of ossicles) that blocks transmission of sound |
| Neural or auditory neuropathy or auditory dyssynchrony | Pathology of the myelinated fibers of the eighth cranial nerve or the inner hair cells that impairs neuroconduction of sound energy to the brainstem. The function of the outer hair cells remains intact. |
| Transient conductive | Debris in the ear canal or fluid in the middle ear that blocks the passage of sound waves to the inner ear |
| Mixed hearing loss | A combination of sensorineural or neural hearing loss with transient or permanent conductive hearing loss |

(tympanic membrane, ossicles, middle ear space, and eustachian tube opening), the inner ear (cochlea and vestibular system), the central auditory pathway (nerve pathways that transmit to the brainstem and cortex), and the auditory cortex (temporal lobes) where sound information is processed. There are anatomic or neural problems that can develop at any point in this pathway that may interfere with the transmission of sound energy and result in a change in the hearing threshold. There are three types of permanent

hearing loss that may be present in the neonate: sensorineural hearing loss, auditory neuropathy (neural hearing loss), and permanent conductive hearing loss, in addition to transient conductive hearing loss (middle ear fluid or debris in the ear canal). Some infants may have a mixed hearing loss that is a combination of two or more types of hearing loss. Types of permanent and transient hearing loss are shown in [Table 109.2](#).

Degrees of hearing loss are determined using clinical audiograms, which evaluate the softest hearing level (HL) thresholds, in decibels (dB). Thresholds between -10 and $+20$ dB HL are considered to be in the normal range, while thresholds above 20 dB are considered diagnostic for mild (20–34 dB), moderate (35–49 dB), moderately severe (50–64 dB), severe (65–79 dB), and profound (>80 dB) hearing loss. Ear and frequency-specific behavioral response hearing testing using a visual reinforcement audiometry (VRA) protocol (conditioned response) can be accomplished beginning at approximately 5 to 6 months of age if this is consistent with the infant's developmental status. Behavioral testing using conditioned play audiometry can be used in children with developmental ages of 3 to 5 years. The official definition of deafness from the Individuals with Disabilities Education Act is “a hearing impairment that is so severe that the child is impaired in processing linguistic information through hearing, with or without amplification.” *Hard of hearing* refers to a hearing loss where there may be enough residual hearing that an auditory device provides adequate assistance to process speech.

Methods for Newborn Hearing Screening

The current methods readily available for newborn screening do not differentiate permanent hearing loss from transient conductive hearing loss. Since the primary objective of newborn hearing screening is to identify permanent hearing loss, this limitation results in an ongoing challenge of false-positive newborn screens and, at times, a delay in the diagnosis of a permanent hearing loss.

**TABLE
109.3****Comparison of Otoacoustic Emissions and Automated Auditory Brainstem Response Screens**

| Characteristics | PHYSIOLOGIC SCREENING METHODS | |
|---|---|--|
| | Otoacoustic Emissions | Automated Auditory Brainstem Response |
| Measurement | Physiologic response of outer hair cells of cochlea | Response in cochlear and auditory neural function to brainstem |
| Detects sensorineural hearing loss | Yes | Yes |
| Detects auditory neuropathy | No | Yes |
| Detects transient and permanent conductive hearing loss | Yes | Yes |
| OAE threshold for fail | 30–35 dB HL | |
| AABR threshold for fail | | 40–45 dB HL |
| Recommended for NICU screens | No | Yes |
| Recommended for well baby screens | Yes | Yes |

AABR, Automated auditory brainstem response; OAE, otoacoustic emissions; NICU, neonatal intensive care unit.

There are currently two objective, noninvasive physiologic measures that are available and reliable for screening newborns and young infants: OAE, either transient or distortion product, and automated auditory brainstem response (AABR) (Cone-Wesson et al., 2000; Gravel et al., 2000; Norton et al., 2000a, 2000b; Johnson et al., 2005).

There are important differences between the two measures as shown in Table 109.3. OAE measures a physiologic response from the cochlear outer hair cells, while AABR measurements reflect both cochlear status, as well as auditory neural function beyond the cochlea to the brainstem. Thus the AABR response reflects activity from a greater portion of the auditory pathway than does the OAE and will detect auditory neuropathy, whereas OAEs do not. Therefore AABR is recommended for screening in the NICU because of the higher incidence of auditory neuropathy among NICU infants (American Academy of Pediatrics, 2007; Maris et al., 2011). Both methods will screen positive for sensorineural hearing loss and permanent conductive hearing loss. Permanent conductive hearing loss is caused by abnormalities of the ossicular chain or Eustachian tube anatomy. Relative to screen fail rates, AABR is more likely to miss borderline or mild hearing loss because of the higher threshold for a pass result (van Zyl et al., 2009).

In addition, both methods screen false positive for permanent hearing loss in the presence of transient retained fluid in the ear canal or middle ear fluid with transient conductive hearing loss (Levit et al., 2015). Uncertainty also may arise with mixed hearing loss, which is a combination of sensorineural or neural hearing loss in conjunction with transient conductive hearing loss. Therefore although the methods continue to improve, limitations remain, supporting the need for ongoing surveillance by the primary care provider. Hearing loss missed by both methods may include mild hearing loss, hearing loss in an isolated frequency range, progressive hearing loss, and late-onset hearing loss (Johnson et al., 2005; Young et al., 2011). A recent study (Levit et al., 2015) of a large longitudinal cohort in the United Kingdom of over 17,000 neonates born from 2013 to 2014 reported that 24% of infants who did not pass a transient evoked OAE screen but passed an AABR screen were subsequently diagnosed with a hearing loss greater

than 45 dB HL using diagnostic ABR. Although current screening methods have limitations, tremendous headway has been made in lowering the age of diagnosis, and newborn hearing screening is now recommended for all infants before discharge from the birthing hospital. In an effort to facilitate diagnosis of the highest risk infants in a timely fashion, a current recommendation is for NICU infants who do not pass their hearing screen to have a diagnostic ABR performed before discharge. This approach facilitates the current Joint Committee on Infant Hearing (JCIH) early hearing detection and intervention (EHDI) recommendation to screen by 1 month, diagnose by 3 months, and provide intervention services by 6 months of age (American Academy of Pediatrics, 2007).

Risk Factors for Permanent Hearing Loss in Infants and Children (Table 109.4)

Although approximately 50% of infants with an identified hearing loss have a risk factor for hearing loss, 50% do not. Therefore ongoing surveillance and rescreening of all infants/toddlers are recommended, with added diligence to those who pass the screen but have a risk factor. Most birthing hospitals currently report risk factors to the primary care provider. However, it may be incomplete since family history is often reported after discharge, and diagnosis of a congenital syndrome may occur postdischarge. Therefore a complete physical and comprehensive review of history of hearing loss with the family after discharge is recommended for all infants.

Although all infants require ongoing surveillance of auditory and speech language skills, infants who pass the newborn screen but have a risk factor will benefit from enhanced surveillance and follow-up with an audiologist experienced in assessing children by 7–12 months of age. This approach is especially important since it is well documented that the rate of identified childhood deafness and hearing loss increases from approximately 1.2 per 1000 in newborns to 3 per 1000 in early school-age children. In a recent report the prevalence of children confirmed as deaf or hard of hearing by school age was 3.65 per 1000 (Prieve et al., 2015).

TABLE 109.4 Risk Factors for Permanent Hearing Loss

| | |
|--|---|
| Family factors | 1. Caregiver concern regarding hearing, speech, language, or developmental delay (Roizen, 1999) 2. Family history of permanent childhood hearing loss (Morton, 1991; Cone-Wesson et al., 2000; Carey and Palumbos, 2016) |
| Neonatal | 3. Neonatal intensive care of more than 5 days or any of the following regardless of length of stay including ECMO (Fligor et al., 2005) 4. In utero infections, such as CMV, herpes, rubella, syphilis, and toxoplasmosis (Vohr et al., 2000; Boppana et al., 2005; Yamamoto et al., 2011) |
| Stigmata, syndromes, and neurodegenerative disorders | 5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone (Wiley et al., 2011) 6. Physical findings, such as white forelock, that are associated with a syndrome known to include a sensorineural hearing loss or permanent conductive hearing loss (Nance, 2003; Wiley et al., 2011; Alford et al., 2014) 7. Syndromes associated with hearing loss or progressive or late-onset hearing loss, such as neurofibromatosis, osteopetrosis, and Usher syndrome (Huang et al., 2012); other frequently identified syndromes including Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson (Nance, 2003; Huang et al., 2012; Carey and Palumbos, 2016) 8. Neurodegenerative disorders, such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome (Wiley et al., 2011) |
| Neonatal or postneonatal | 9. Culture-positive postnatal infections associated with bacterial and viral (especially herpesviruses and varicella) meningitis (Roizen, 2003; Hille et al., 2007) |
| Postneonatal | 10. Head trauma, especially basal skull/temporal bone fracture that requires hospitalization (Bergemalm, 2003; DeMarcantonio and Choo, 2015) 11. Chemotherapy (Gruss et al., 2012) |

CMV, Cytomegalovirus; ECMO, extracorporeal membrane oxygenation.

Family Factors

Risk Factor 1

Parent or caregiver concern about child hearing, speech, language, or developmental delay has consistently been shown to be a reliable predictor of hearing loss (Roizen, 1999).

Risk Factor 2

A history of family members who are deaf or hard of hearing with onset in childhood (Morton, 1991; Cone-Wesson et al., 2000; Alford et al., 2014; Carey and Palumbos, 2016) has high predictive value and is associated with known genetic causes including connexin 26 mutations. It has been shown that young parents may not be informed of a family history until after their infant is diagnosed with a hearing loss. Monitoring is based on etiology, with a diagnostic evaluation recommended by no later than 7–9 months of age (Nance and Kearsey, 2004; Morton and Nance, 2006; Bush et al., 2014).

Neonatal

Risk Factor 3

Includes infants who require care in the NICU or special care nursery for more than 5 days, which is used as an indicator of illness severity (American Academy of Pediatrics, 2007). This broad category encompasses most other medical risk factors including prematurity, perinatal asphyxia, and a requirement for extracorporeal membrane oxygenation. All infants with hyperbilirubinemia requiring an exchange transfusion, regardless of length of stay, are included in this risk category (Shapiro, 2003; Shapiro, 2005). Use of aminoglycosides for less than 5 days is not a risk factor.

Risk Factor 4

Includes in utero infections. Follow-up of herpes, rubella, syphilis, and toxoplasmosis is recommended by 7–9 months of age.

Cytomegalovirus (CMV) infection is a leading cause of congenital infection occurring in 0.2%–2% of live births worldwide and is a leading cause of nongenetic unilateral or bilateral early, progressive, and delayed-onset sensorineural hearing loss (Yamamoto et al., 2011; Cannon et al., 2014; Ross et al., 2014). The recommendation for CMV infection is longitudinal follow-up and assessment of language and hearing skills by the primary care provider and audiologist.

Stigmata, Syndromes, and Neurodegenerative Disorders

Risk Factors 5 and 6

Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies (Bergemalm, 2003; Wiley et al., 2011), and physical findings such as white forelock that are associated with a syndrome known to include a sensorineural hearing loss or permanent conductive hearing loss, have a significant amount of overlap, and infants with these findings are at increased risk of neonatal and later onset hearing loss.

Risk Factors 7 and 8

Syndromes associated with hearing loss or progressive or late-onset hearing loss, such as neurofibromatosis, osteopetrosis, and Usher syndrome (Roizen, 2003), and other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson. There are more than 400 syndromes and genetic disorders associated with hearing loss (Morton, 1991; Morton and Nance, 2006; Schrijver and Gardner, 2006; Siemerling et al., 2006). Neurodegenerative disorders, such as Hunter syndrome, and sensory-motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome, are strongly associated with permanent hearing loss (Roizen, 2003). Consultation with a

geneticist is indicated for all infants diagnosed with congenital hearing loss for whom there is not a clear etiology.

Neonatal or Postneonatal

Risk Factors 9, 10, and 11

May occur in the neonatal period or postdischarge.

Risk Factor 9

Culture-positive bacterial and viral (especially herpesviruses and varicella) postnatal infections including meningitis may result in rapid-onset hearing loss (Stevens et al., 2003; Westerberg et al., 2008; Bassler et al., 2009; Cohen et al., 2014). Widespread administration of conjugate vaccines has resulted in decreased rates of *Haemophilus influenzae* type B infection, pneumonia, measles, mumps, rubella, and childhood meningitis; however, encephalitis viral infections (especially herpesviruses) and varicella remain serious risk factors (Cohen et al., 2014). Children with cochlear implants remain at increased risk of postnatal infection (Biernath et al., 2006).

Risk Factors 10 and 11

Head trauma, especially basal skull/temporal bone fractures that require hospitalization, and particularly injury to the mastoid, is associated with trauma-associated hearing loss (Bergemalm, 2003). Hearing loss among pediatric cancer patients as a consequence of treatment with chemotherapy and radiation is common, and these children should be closely monitored for hearing loss (Gruss et al., 2012).

After Newborn Hearing Screening: Audiology Diagnostic Protocols

In 1999 the American Academy of Pediatrics endorsed EHDI, defined as screening by 1 month, diagnosis by 3 months, and appropriate intervention services by 6 months of age. The recommended audiology diagnostic assessment for infants who do not pass the newborn screen includes the following battery of tests (American Academy of Pediatrics, 2007):

1. Click-evoked ABR testing using both condensation and rarefaction single-polarity stimulus, if there are risk indicators for neural hearing loss (auditory neuropathy).
2. OAEs, either distortion product or transient evoked.
3. Tympanometry using a 1000-Hz probe tone.
4. VRA, not until 7–9 months of age.
5. Clinician observation of the infant's auditory behavior may be used as a cross check for the electrophysiologic measures. Behavioral observation alone is not adequate for determining whether hearing loss is present and is not adequate for the fitting of amplification devices.

Identification of an audiologist with skills in pediatric diagnostic assessment can be obtained from the EHDI–pediatric audiology links to services (PALS) website: <http://www.ehdipals.org/>. The report from the audiologist will include the type of hearing loss, whether the loss is unilateral or bilateral, and the degree of hearing loss.

Medical Workup for Hearing Loss

A visit should be scheduled with the family as soon as a diagnosis of hearing loss is made by the audiologist, to discuss the audiologist's report, provide information on community supports and intervention resources, and provide support for the family during a period

of stress. During the visit with the family, the physician reviews the pregnancy, neonatal, and family history for hearing loss and reexamines the child for evidence of any craniofacial abnormalities or a syndrome associated with hearing loss.

The evaluation of all children with a diagnosis of hearing loss or suspected of hearing loss should include a complete physical with thorough examination of the head, eyes, ears, nose, and throat and an evaluation of middle ear status. It is not uncommon for newborns and NICU graduates to have middle ear effusion or retained amniotic fluid, which can cause transient conductive loss and a false-positive screen. Persistence of middle ear fluid in the infant should be monitored and managed in the medical home. In persistent cases of middle ear fluid, myringotomy placement will be necessary to complete a valid diagnosis to rule out a concurrent permanent hearing loss. There is evidence that persistent middle ear fluid identified in the NICU is a risk factor for chronic otitis media with effusion in the first year (Doyle et al., 2004). Knowledge and review of the JCIH (American Academy of Pediatrics, 2007) risk factors of both syndromic and nonsyndromic hearing loss and associated physical abnormalities is essential. Once the diagnosis of a permanent hearing loss is established, it is necessary to discuss the benefits of early intervention (EI) services and amplification. The primary care physician therefore needs to be aware of all community resources and support the family choice of EI program and mode of communication.

Multidisciplinary Team

Consultations are recommended and facilitated with otolaryngology and genetics specialists. Every infant with confirmed hearing loss should be evaluated by an otolaryngologist with knowledge of pediatric hearing loss. The otolaryngologist conducts a comprehensive assessment to determine the etiology of hearing loss and provides recommendations and information to the family, audiologist, and primary care provider on candidacy for amplification, assistive devices, and surgical intervention, including reconstruction, bone-anchored hearing aids, and cochlear implantation.

The otolaryngologist will order required radiographic imaging. Temporal bone imaging is indicated as part of the work-up to aid in identifying the etiology, any malformations that may need surgical intervention, and appropriateness of amplification or cochlear implantation. High-resolution computed tomography is appropriate for assessing the osseous structures of the external auditory canal and middle ear, and magnetic resonance imaging (MRI) is optimal for evaluating soft tissue and cranial nerves.

Because of the prevalence of hereditary hearing loss, all family members of children with confirmed hearing loss should be offered a genetics evaluation and counseling. This evaluation can provide families with information on etiology, prognosis, associated disorders, and recurrence in offspring. The geneticist will review the family history for specific genetic disorders or syndromes and complete genetic testing for syndromes or gene mutations for nonsyndromic hearing loss such as *GJB2* (Connexin 26) (Erbe et al., 2004; Santos et al., 2005; Siemerling et al., 2006; Alford et al., 2014).

Because 30%–40% of children with confirmed hearing loss have developmental comorbidities, developmental milestones should be closely monitored and referrals initiated to developmental specialists for suspected disabilities as needed. It is also recommended that each child with a permanent hearing loss have at least one examination by an ophthalmologist experienced in evaluating infants because of the association of hearing loss with

TABLE 109.5 Characteristics of Modes of Communication

| Mode | Mechanism | Language Goal |
|-------------------------------|--|---|
| Auditory oral communication | The use of residual hearing and amplification with visual support (speech reading) | Spoken |
| Auditory verbal communication | Based on listening skills alone | Spoken |
| Cued speech | Uses visual communication and combines listening with eight hand shapes in four placements near the face | Spoken |
| Total communication | Combines all means of communication and encourages simultaneous use of speech and sign | Spoken and sign |
| American Sign Language | Visual and manual | ASL, English learned as a second language |

ASL, American Sign Language.

vision impairments and the importance of vision for children with hearing loss.

Communication Options

EI providers, including teachers of the deaf, the speech–language pathologist, and audiologist, will provide information to the family on communication options consistent with the child’s diagnosis. The family needs to decide on the communication mode that will work optimally for the child and family. There are five options described in [Table 109.5](#): auditory oral communication (speech reading), auditory verbal communication, cued speech, total communication, and American Sign Language (ASL). Parents may initiate with total communication and change mode subsequently as the child progresses depending on the child’s progress with communication. For example, the family of a child with profound hearing loss may initially choose total communication but, after a cochlear implant at 12 months of age, may use predominantly auditory verbal or auditory oral communication.

Amplification

Hearing Aids

Infants as young as 1 month of age can be fitted with hearing aids. Hearing aids are compact and worn either in-the-ear or behind-the-ear. Components are the microphone that picks up sounds and the amplifier. The audiologist uses computer programming to adjust the sound for an individual child’s needs. If the child has different degrees of hearing loss at different frequencies, the

audiologist adjusts the gain (loudness). The young growing infant needs to be seen by the audiologist approximately every 6 weeks to replace outgrown molds.

Frequency-Modulated Systems

Frequency-modulated (FM) systems were developed to enhance hearing in noisy environments. An FM system consists of a small radio transmitter attached to a microphone and a small radio receiver. A parent, EI provider, or teacher wears the FM transmitter and microphone while the infant/child wears the FM receiver. The FM transmitter sends a low-power radio signal to the FM receiver, which needs to be within 50 feet of the transmitter. The FM receiver receives the signal from the microphone and sends it to a personal hearing aid or cochlear implant. Listening to the FM signal is similar to listening to speech only inches away. Systems can be used in the home, while shopping, or at school.

Cochlear Implants

Children 12 months and older who are deaf or severely hard of hearing are approved by the US Food and Drug Administration to receive cochlear implants. As of December 2012, roughly 58,000 devices had been implanted in adults and 38,000 in children in the United States (<https://www.nidcd.nih.gov/health/cochlear-implants>). It is currently recommended that the child be adequately fitted with hearing aids for 3–6 months before determining implant candidacy. A lack of benefit in the development of auditory skills with amplification using hearing aids needs to be demonstrated to determine eligibility for an implant. There are increasing reports ([Philips et al., 2009](#); [Meister et al., 2015](#)) demonstrating the beneficial effects on speech and language for infants with bilateral profound hearing loss who are implanted before 12 months of age.

Because of an increased risk for bacterial meningitis, it is recommended that physicians monitor all patients with cochlear implants (particularly children whose implants have a positioner) for middle ear and other infections ([Reefhuis et al., 2003](#); [Wilson-Clark et al., 2006](#); [Rubin and Papsin, 2010](#)). *Streptococcus pneumoniae* is the most common pathogen causing meningitis in cochlear implant recipients ([Bluestone, 2003](#); [Centers for Disease Control and Prevention, 2003](#); [Biernath et al., 2006](#); [Glikman et al., 2009](#)). All children with cochlear implants should be vaccinated according to the American Academy of Pediatrics high-risk schedule (<https://www.aap.org/en-us/Documents/immunizationschedule2017.pdf>).

Comprehensive Early Intervention

All infants diagnosed with a permanent hearing loss should be referred and enrolled in EI by 6 months of age to minimize the deleterious effects of communication deprivation ([Moeller, 2000](#); [Yoshinaga-Itano, 2003a, 2003b](#); [Vohr et al., 2011](#)). The JCIH recommends that states should have a single point of entry into intervention specific for children with hearing loss, to ensure that, regardless of geographic location, all families who have infants or children with hearing loss receive information about a full range of options regarding amplification and technology, communication and intervention, and accessing appropriate counseling services ([American Academy of Pediatrics, 2007](#); [Yoshinaga-Itano, 2014](#)).

The JCIH published 12 best practice guidelines for EI programs ([Yoshinaga-Itano, 2014](#)). These include the following:

- The provision of timely referral to EI services with providers who have knowledge and skills in early childhood deafness and hearing loss.
- Infusion within the system of partnerships with parents as well as professionals who are (deaf/hard of hearing).
- Longitudinal developmental assessments for monitoring the child's development.
- Data management systems that include developmental outcomes.
- A process to monitor the fidelity of the intervention.
- Appropriate services for children with additional disabilities, those from non-English speaking families, and those from special populations, including unilateral hearing loss and auditory neuropathy/dyssynchrony.

As the number of bilingual children with hearing loss continues to increase, the question has arisen regarding the optimal way for EI providers to teach speech to children with hearing loss who are bilingual. A number of investigators have reported that children with hearing loss supported in both their home language and the majority culture language compared with children with hearing loss exposed to majority language alone acquired English and the primary home language at similar rates (Waltzman et al., 2003; Guiberson, 2014). Two studies (Bunta and Douglas, 2013; Bunta et al., 2016) investigated the effects of supporting both the home language (Spanish) and the language of the majority culture (English) on language outcomes in bilingual children with hearing loss who used cochlear implants and hearing aids compared with bilingual peers who received English-only support. Bilingual children who received dual-language support outperformed peers who received English-only support as measured by the Total Language and Expressive Communication language age scores of the Preschool Language Scales 4. Because of the high incidence of hearing loss

among Hispanics in the United States, it is likely there will be an increased need for provision of dual-language EI services (Mehra et al., 2009).

In addition, a total communication approach including ASL and speech is recommended at the initiation of EI services to ensure access to language. An expert opinion summary proposes consideration of the use of both sign and spoken language for all young children who are deaf to ensure access to language and linguistic competence. Napoli et al. (2015) reviewed findings demonstrating that sign language development is associated with both written and spoken language development (Knors and Marschark, 2012; Rinaldi et al., 2014).

Neonatal Intensive Care Unit Infants and Hearing Loss

The majority of infants cared for in an NICU have a risk factor for hearing loss. The relationship between risk factors and hearing loss in several studies of NICU infants is reviewed, and summaries are shown in Table 109.6. The study by Robertson et al. (2009) included a cohort of 1279 infants weighing 1250 grams and below or at 28 weeks' gestation screened with AABR followed by audiology diagnostic assessment and followed to 5 years of age. The rate of permanent hearing loss was 3.1%, rate of severe to profound was 1.9%, 28% had progressive hearing loss, and 73% had other disabilities. Risk factors included prolonged oxygen use, gastrointestinal surgery, patent ductus arteriosus ligation, and low socioeconomic status (SES).

Schmidt et al. (2003) published two studies examining the effects of the major neonatal morbidities of bronchopulmonary dysplasia (BPD), major brain injury, and severe retinopathy of

TABLE 109.6 Risk Factors and Rates of Hearing Loss Among Infants Cared for in a Neonatal Intensive Care Unit

| Author | Dates of Birth | Sample | Screen | Age of Diagnostic Follow-Up | Risk Factors for HL | Rates of Hearing Loss | |
|---------------------------|----------------|-----------------------|--------|-----------------------------|--|-----------------------|-------|
| Robertson et al., 2009 | 1974–2003 | ≤28 weeks and ≤1250 g | AABR | 3 years | BPD; gastrointestinal surgery; patent ductus ligation; low SES | All degrees HL | 3.1% |
| | | | | | | Severe to profound | 1.9% |
| Schmidt et al., 2003 | 1996–1998 | 500–1250 grams | AABR | 18 months | 3 major morbidities: BPD, brain injury, and severe ROP | BPD | 3.5% |
| | | | | | | Brain injury | 2.9% |
| | | | | | | Severe ROP | 3.8% |
| Schmidt et al., 2015 | 1996–1998 | 500–1250 grams | AABR | 5 years | # of morbidities: BPD, brain injury, and severe ROP | No risk factor | 1.3% |
| | | | | | | 1 risk factor | 3.6% |
| | | | | | | 2 risk factors | 5.4% |
| | | | | | | 3 risk factors | 25.0% |
| Van Dommelen et al., 2015 | 1998–2012 | <32 weeks | AABR | 2–4 months | Lower weeks of gestational age | 24.0–24.9 | 7.5% |
| | | | | | | 25.0–25.9 | 5.2% |
| | | | | | | 26.0–26.9 | 4.6% |
| | | | | | | 27.0–27.9 | 2.8% |
| | | | | | | 28.0–28.9 | 2.0% |
| | | | | | | 29.0–29.9 | 1.6% |
| | | | | | | 30.0–30.9 | 2.0% |
| | | | | | | 31.0–31.9 | 1.2% |
| Morris et al., 2008 | 2002–2005 | ≤1000 grams | ABR | 18–22 months | Hyperbilirubinemia with aggressive and conservative photo therapy (PT) | Aggressive PT | 1.0% |
| | | | | | | Conservative PT | 3.0% |

AABR, Automated auditory brainstem response; BPD, bronchopulmonary dysplasia; HL, hearing loss; ROP, retinopathy of prematurity; SES, socioeconomic status.

prematurity (ROP) on rates of hearing loss at 18 months in very low-birth-weight infants weighing less than 1250 grams. Rates of hearing loss compared with not having the risk factor were 3.5% versus 1.4% for BPD, 2.9% versus 2.2% for brain injury, and 3.8% versus 2.2% for severe ROP. In the second study children were followed to 5 years of age (Schmidt et al., 2015). Overall, 2% of the 1514 infants weighing between 500 and 1250 grams were described as deaf. Rates of deafness were related to the risk factors of BPD, serious brain injury, and severe ROP. In this report the investigators identified a relationship of rate of hearing loss with an increasing number of risk factors (no risk factors: 1.3%, one: 3.6%, two: 5.4%, and three: 25%).

Van Dommelen et al. (2015) reported on the relationship between gestational age and hearing loss in a large cohort of 18,564 preterm infants. The prevalence of hearing loss consistently increased with decreasing week of gestation from 1.25% at 31 weeks to 7.55% at 24 weeks. The study of Morris et al. (2008) examined the effects of two protocols to provide phototherapy to very preterm infants with hyperbilirubinemia. Compared with the conservative-phototherapy group, the aggressive-phototherapy group had significant reductions in the rate of severe hearing loss, from 3% to 1%. The conclusion was that the benefit to decreased impairment may be offset by the increased mortality in the smallest infants. All of the studies indicate that there are increased rates of hearing loss among NICU infants who are the most preterm and have the highest rates of neonatal morbidities.

The Brain, Language Outcomes, and Access to Language

The most important predictor of improved language outcomes is early age of identification. Age of identification reported in the 1980s and 1990s ranged from 19 months to 31–35 months (Coplan, 1987; Mace et al., 1991). Since 1997 the age of identification in some reports has dropped to 2–4 months (Vohr et al., 2002; Johnson et al., 2005). The National CDC EHDI data for 2013 indicated that 69% of newborns who did not pass the newborn screen and who were diagnosed with a permanent hearing loss were diagnosed by 3 months of age. This rate may in part be due to incomplete reporting but indicates how some parts of the country continue to struggle in achieving the EHDI 1–3–6 goal. (<https://www.cdc.gov/ncbddd/hearingloss/data.html>). Enrollment in EI by 6 months remains a critical EHDI goal as earlier age is consistently associated with improved outcomes for children who are deaf or hard of hearing (DHH).

Yoshinaga-Itano et al. (2001, 2010) have shown that early quality intervention services in the first year of life that provide access to language (either speech or visual [ASL]) improve the language and developmental outcomes for children who are deaf or hard of hearing. The longitudinal study of Moeller (2000) showed in adjusted analyses that enrollment in EI services and greater family involvement predicted higher vocabulary scores on the Peabody Picture Vocabulary test at 5 years of age among DHH children in Nebraska. The most recent CDC data for 2014 indicate that of those diagnosed with permanent hearing loss, 88% were referred to EI, 65% were receiving EI and of those 68% were referred by 6 months of age (<https://www.cdc.gov/ncbddd/hearingloss/data.html>).

The first 3 years of life are particularly critical for access to language since this period is a time of both rapid language and brain growth. In addition, it is not in the ears but the brain where language is processed and understood. During the first 3 years of

life, the brain grows and matures in complexity and connectivity at an incredible rate that is in part mediated by the infant's exposure to language. Sharma et al. (2002, 2005) have shown that earlier implantation of a cochlear implant is associated with more optimal development of the auditory pathway to the auditory cortex (temporal lobes). Children who are deaf and born to deaf parents have natural early exposure to visual language (ASL). However, more than 90% of children born DHH are born to hearing parents and do not have immediate access to either visual language (ASL) or auditory language (speech). Therefore early access to language and EI that meets the communication needs of the family is the key. The studies of Hart and Risley (1995) have shown that the amount and quality of language that all children are exposed to in the home in the first 3 years of life vary significantly, and the greater the input of child-directed quality language, the more optimal the child's language and cognitive outcomes.

Further evidence of the importance of language access comes from the studies of the neuronal maturation of the central auditory pathway (Sharma et al., 2002, 2005). In the absence of typical auditory stimulation, the auditory pathway and cortex remain maximally sensitive and plastic for development for about 3.5 years in response to placement of a cochlear implant. From 3.5 to 7 years response to a cochlear implant drops to 7%–30% and after 7 years to less than 5%. These data identify that the window of opportunity and plasticity for development of the auditory pathway and speech for a child with a severe to profound hearing loss is the first 3.5 years of life. In addition, MRI studies suggest that cross-modal reorganization of the auditory cortex occurs in DHH children without auditory stimulation, in response to visual and somatosensory stimulation. It is suggested that this modification in brain development may facilitate enhanced processing of skills in these domains for DHH (Sharma et al., 2005). Evidence of very early impact has been shown in infants who are DHH exposed to visual language, who develop sign babbling at the rate at which hearing infants develop verbal babbling (Petitto et al., 2004).

A study by Tomblin et al. (2015) on the usage characteristics of amplification identified that a combination of factors, including earlier age of fitting, higher daily duration of amplification, and greater audibility of the device, were all significantly associated with higher early language skills in a cohort of children with mild to severe hearing loss. Another important finding, however, was that children fitted with hearing aids after 18 months of age were able to improve their language abilities as a function of increased duration of hearing aid use. This finding again suggests that brain plasticity and the language learning system remain open to experience provided by increased access to linguistic input during the preschool years. Data from Tomblin et al. (2015) also indicate that the development of language for children with a more severe hearing loss is more challenging than in children with a mild loss. Within a cohort of children divided into mild (25–45 dB HL), moderate (45–60 dB HL), or moderate to severe (>60 dB HL) hearing loss, compared with age- and SES-matched controls, children with moderate to severe hearing loss consistently had the lowest language scores at 2–5 years of age. For all of the HL groups, a greater degree of hearing loss was associated with lower language abilities.

Additional factors shown to contribute to language success in children include enhanced maternal communicative intent (Vohr et al., 2010), higher SES, higher parent education level (Hart and Risley, 1995), less parental stress (Quittner et al., 2010), a more optimal home-language environment (Vohr et al., 2014), and access to deaf role models (Yoshinaga-Itano, 2014).

In summary, EHDI systems of care continue to improve access to timely screening, diagnosis, and EI services to ensure successful outcomes. It is expected that ongoing surveillance and facilitation of individualized coordinated care with the use of the electronic medical record, multidisciplinary partnering and implementation of both local and telemedicine services (Dharmar et al., 2015), and coordination with state EHDI programs will continue to contribute to improved outcomes.
